## ABSTRACT

Mechanical behavior analysis of the friction stir weld nugget of an aluminum alloy 2050 reveals a major role of the microstructure which varies with the distance to the weld surface. Three types of microstructure heterogeneities are considered namely grain size, precipitation state and textured bands. The grain size and the T1 precipitates density decrease with the distance from the weld surface. The density of T1 precipitates has a first order effect on micro-hardness variations and makes the Hall-Petch rule not valid in this case. Tensile tests combined with strain field identification done by digital image correlation measurements demonstrate the good correlation between textured bands and strain field heterogeneities. Crystal plasticity simulations by finite element method well account for the macroscopic mechanical behavior as well as strain field in textured bands.

## 1. Introduction

Friction stir welding (FSW) of aluminum alloys is becoming a mature and robust process and has extended the use of welding in particular for 2xxx and 7xxx alloys in aeronautic industry. In addition, FSW is very efficient where it is necessary to join different aluminum alloys. Applied for example on lightweight aluminum lithium alloys [1], this welding technique could significantly reduce the weight of aerospace structures by limiting the use of rivets, fasteners and overlapping areas. Exhaustive review on the principles of FSW and on the properties of welds, as well on potential industrial applications in shipbuilding, offshore, railways, automotive and so on, was proposed in [2,3]. Friction stir-welded joints consist of three zones involving specific microstructures, namely heat affected zone (HAZ), thermo-mechanically affected zone (TMAZ) and weld nugget (WN). The weld nugget is the dynamically recrystallized region of the TMAZ resulting in a fine equiaxed microstructure [4]. Key microstructural parameters such as precipitation state influencing local hardness within the weld joints were clearly identified on AA2199 and AA2024 [5,6]. A big effort in modeling the in-process temperature evolution, the

microstructure evolution, the strain hardening and some damage processes devoted to the FSW of 6xxx series aluminum alloys has resulted in an integrated modeling framework [7]. Different modes of degradation of the weld joints were studied. The effect of residual stress as well as the microstructure on the fatigue behavior was approached in [8,9]. The corrosion behavior was recently analyzed by accounting for the reactivity of the different domains of the joint [10,11]. The galvanic coupling level was associated to the local corrosion potential, the microstructure and the hardness. The galvanic coupling was also shown to be affected by the heterogeneous stress field induced by external mechanical loading. More specifically on the welding of 2050 aluminum alloys, post-welding heat treatment significantly changes the corrosion behavior of the base metal leading to an inversion in the galvanic coupling [12]. The intrinsic properties of the weld nugget were less studied. In this region, metallographic observations reveal commonly elliptical periodical features often termed “onion rings”. These onion-rings were assimilated to bands having either different precipitation states [13], modified average grain size [14], or a variation of crystallographic texture [15]. On 2050 alloy, galvanic corrosion was identified between these bands [16]. The other important effect of the onion rings was observed on 2050 weld nugget under stress corrosion cracking condition [17]. During slow strain rate tests (uniaxial loading in the *L* direction at a strain rate of  $10^{-6} \text{ s}^{-1}$  in 1.0 M NaCl aerated solution at room temperature), intergranular stress corrosion cracking occurs along the *T* direction

on the  $L-T$  surface of the flat tensile specimens. Electron Back Scattered Diffraction (EBSD) analysis of the surroundings of the cracks showed that the long cracks initiate and propagate along the interface of textured bands corresponding to onion rings. The question of the effect of the local variation of the texture on the stress/strain field heterogeneity was proposed as one of the key issues to be addressed. Experiments combined with numerical approaches try to provide a description of stress/strain field heterogeneity in 2050 weld nugget.

## 2. Material and methods

The material used in this work is a weld nugget obtained by friction stir welding of two 15 mm thick sheets of AA2050 T3 (solutionizing, quenching and stretching), submitted to a post-welding heat treatment at 155 °C during 30 h. Nugget microstructure heterogeneities in the depth were analyzed from samples machined in section perpendicular to the welding direction, mechanically polished up to 1/4  $\mu\text{m}$  using OP-S solution and etched during 2 min in a solution of 40 ml of tetrafluoroboric acid ( $\text{HBF}_4$ ) and 760 ml of distilled water with a current density of 0.2 A  $\text{cm}^{-2}$ . Then, the samples were observed using an optic microscope (Olympus PMG3). The T1 precipitation was quantified by the SIMaP laboratory in the European synchrotron radiation facility (ESRF) in Grenoble by Small Angle X-ray Scattering (SAXS) measurements [18]. Nugget microstructure in the welding direction is characterized using tensile specimens machined in the nugget zone, by series of 6 specimens in the depth (see Fig. 1). All specimens were mechanically polished up to 1/4  $\mu\text{m}$  using OP-S solution. Electron Back Scattered Diffraction (EBSD) maps (EDAX's high sensitivity EBSD camera) were performed along the gauge length of the tensile specimens, before testing. The size of the maps is about 1500  $\mu\text{m} \times 400 \mu\text{m}$  with a step of 2  $\mu\text{m}$ .

Mechanical heterogeneities were highlighted by Vickers microhardness measurements and tensile tests. Vickers microhardness maps  $\text{Hv}_{0.5}$  were performed in the section perpendicular to the welding direction of the weld nugget with a step of 0.5 mm, using a Duramin A300D Struers microhardness tester. After EBSD

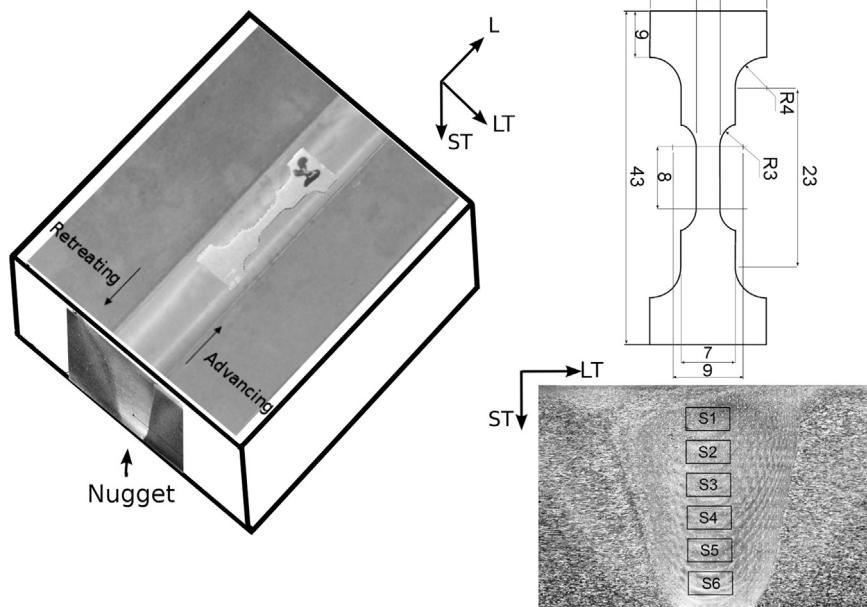

measurements, tensile tests were conducted at a strain rate of  $\dot{\epsilon} = 5 \cdot 10^{-5} \text{ s}^{-1}$  on a 5kN Deben Microtest tensile stage. The specimens were instrumented with gauges to measure strain between 0 and 2%. For more than 2%, strain was determined using a LVDT displacement measurements. Local strain fields were obtained using Digital Image Correlation (DIC) method and the software Correl<sup>04</sup>. Before tensile tests, the specimens were electrolytically etched in a  $\text{HBF}_4$  solution, allowing creation of a texture favorable for DIC measurements. A digital microscope KEYENCE VHX-1000E was used as an in situ surface observation technique taking one image every 15 s during the tensile test (for a  $\Delta\epsilon = 7.5 \cdot 10^{-4}$ ). To obtain displacement fields of the deformed image with respect to a reference image, the region of interest of 1600 px  $\times$  1200 px (1 pixel = 1  $\mu\text{m}$ ), containing the EBSD map zone, was partitioned into sub-images, called zone of interest (ZOI), of 32  $\mu\text{m} \times$  32  $\mu\text{m}$ . The correlation principle is used to compare the ZOI in both images, allowing the calculation of the mean value of the local strain on about 10 grains.

## 3. Modeling

In order to understand the origin of the strain fields heterogeneities, a finite element model was built using the code ZeBuLoN [19]. The details of the geometry and mesh are given in Section 4.3. The mechanical behavior of the nugget was described by a crystal elasto-plasticity model taking into account 12 slip systems for the FCC crystal, as proposed by Cailletaud et al. [20]. Anisotropic elasticity was used to described the elastic behavior. For the nugget microstructure, cubic elasticity coefficients of pure aluminum were considered ( $C_{1111}=108 \text{ GPa}$ ,  $C_{1122}=28.3 \text{ GPa}$ ,  $C_{1212}=62 \text{ GPa}$ ). At the grain scale, inelastic deformation mainly results in slip on the possible slip systems of the crystal. The resolved shear stress  $\tau_s$  on each slip system  $s$  is given by the following equation:

$$\tau_s = \underline{\underline{\sigma}} : \underline{\underline{m}}^s \quad \text{with} \quad \underline{\underline{m}}^s = \frac{1}{2}(\vec{n}^s \otimes \vec{l}^s + \vec{l}^s \otimes \vec{n}^s) \quad (1)$$

where  $\vec{n}^s$  and  $\vec{l}^s$  are the slip plane normal and the slip plane

**Fig. 1.** Location of the tensile specimen sampling in the  $L-LT$  and  $LT-ST$  plane of the weld. Tensile specimen dimensions in millimeter (thickness: 1.5 mm).

direction, respectively. Cailletaud et al. [20] proposed a phenomenological formulation for the flow rule and the hardening law, based on thermodynamics of irreversible processes. The plastic flow rate  $\dot{\gamma}_s$  on the slip system  $s$  is given by the following equation:

$$\dot{\gamma}_s = \left( \frac{|\tau_s| - \tau_s^c}{K} \right)^n \text{sign}(\tau_s) \quad (2)$$

where  $K$  and  $n$  characterize the material rate sensitivity and  $\tau_s^c$  the resolved shear stress threshold. In this work, only monotonic loading was considered. Consequently, the evolution of the critical resolved shear stress could be described by a nonlinear isotropic hardening law:

$$\tau_s^c = \tau_0^c + Q \sum_r h_{rs} (1 - e^{-b\nu_r}) \quad \text{with } \nu_r = \int_0^t |\dot{\gamma}^r| dt \quad (3)$$

The parameters  $\tau_0$ ,  $Q$  and  $b$  were optimized by fitting the results obtained from the finite element calculations and the experimental tensile test curve. To do that, a part of  $800 \times 200 \times 6 \mu\text{m}^3$  of the gauge length was modeled by a rectangular aggregate regularly meshed with cubic elements of  $6 \times 6 \times 6 \mu\text{m}^3$ . The crystal orientations were attributed to the Gauss point according to the EBSD map. The obtained crystal plasticity model coefficients are the following:  $K=50 \text{ MPa s}^{1/n}$ ,  $n=25$ ,  $\tau_0^c=66 \text{ MPa}$ ,  $Q=50.0$ ,  $b=40$ . Self-hardening and latent hardening due to interactions between slip systems are introduced by the matrix  $h_{rs}$ . In this case, the interaction matrix was simplified by using Taylor hardening hypothesis ( $h_{rs}=1$ ).

## 4. Results

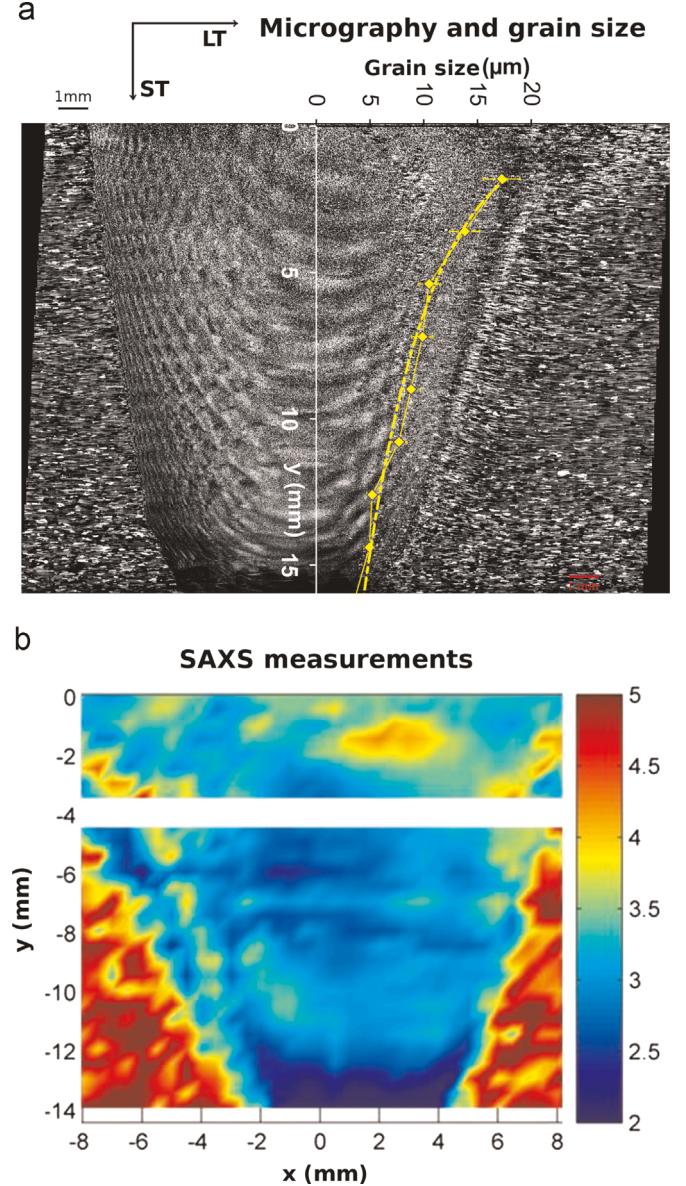

### 4.1. Microstructural heterogeneities

#### 4.1.1. Microstructural heterogeneities in the LT-ST plane

After mechanical polishing and etching, some characteristics of the microstructure are revealed and are visible by optic microscopy (Fig. 2a). At the scale of the weld joint, the cross sections of the “onion rings” have pseudo-elliptic shapes and are arranged periodically. In the central ST direction of the weld joint, these onion rings are periodically spaced of about  $500 \mu\text{m}$ . The analysis at lower scale shows that the microstructure is composed of equiaxed grains with sizes decreasing from  $17 \mu\text{m}$  at the top of the weld down to  $4 \mu\text{m}$  at the bottom of the weld (yellow curve in Fig. 2a). These data are consistent with those reported in the literature [4,21]. By applying SAXS techniques (Small Angle X-Ray Scattering) at the ESRF (European Synchrotron Radiation Facility) on the weld joint of the same material, the density of T1 hardening precipitates was estimated to decrease from the top to the bottom of the nugget [18].

#### 4.1.2. Microstructural heterogeneities in the L-LT plane

EBSD on the L-LT plane and in the middle of the weld nugget (Fig. 3) shows clearly that the onion ring sections correspond to domains of material having different textures. The periodicity of the texture bands corresponds to the one observed on the LT-ST section. Two types of periodical bands are distinguished and are characterized by an orientation distribution function (ODF) in the plane  $\phi_2=45^\circ$ . Type A bands contain the orientation  $(112)[1\bar{1}0]$  of the alpha fiber and the orientation  $(110)[1\bar{1}0]$ . Type B bands contain directions  $(111)[1\bar{1}0]$  and  $(111)[0\bar{1}1]$  of the gamma fiber. These results are consistent with the fact that the texture is one of the major microstructural features of the different bands in the onion rings structure [15].

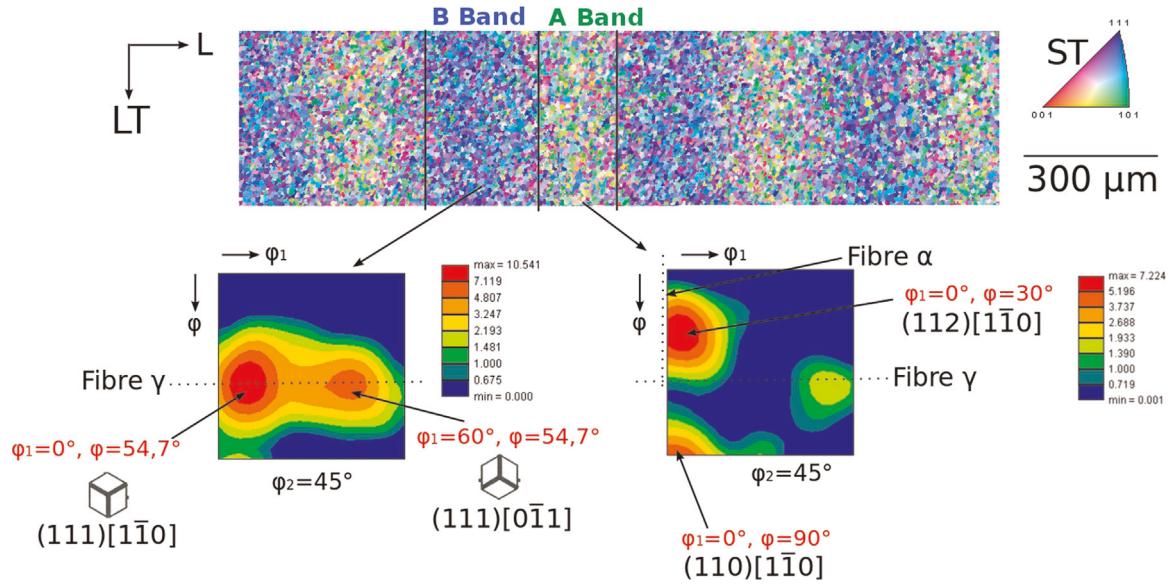

**Fig. 2.** (a) Grain size and (b) T1 precipitates density variations in the weld nugget [18]. (For interpretation of the references to color in this figure caption, the reader is referred to the web version of this paper.)

### 4.2. Heterogeneities of mechanical behavior

#### 4.2.1. Mechanical properties along L direction according to the position in the weld nugget

To analyze the mechanical behavior of the weld nugget, uniaxial tension tests were done at the strain rate of  $5 \text{ 10}^{-5} \text{ s}^{-1}$  on specimens machined at different distances from the weld surface (specimen S1-S6). Each test was reproduced three times in the same conditions. The gauge length of the tensile specimens is 8 mm and the cross section area is about  $4.5 \text{ mm}^2$ . In the gauge length, the specimen contains about 30 textured bands and there are about  $45 \cdot 10^3$  grains in the cross section. The characteristic mechanical data (Young modulus  $E$  (GPa), the yield strength  $R_{p0.2}$  (MPa), the fracture stress  $R_m$  (MPa) and the strain at rupture  $A$  (%)) given in Fig. 4 are then considered to be representative of the macroscopic behavior of the weld nugget in the  $L$  direction at the different sampling levels. No significant variation is observed for  $E$ ,  $R_{p0.2}$  and  $R_m$ . The average values of  $E$ ,  $R_{p0.2}$ ,  $R_m$  are 70 GPa, 310 MPa and 410 MPa, respectively. Considering the decrease of grain size

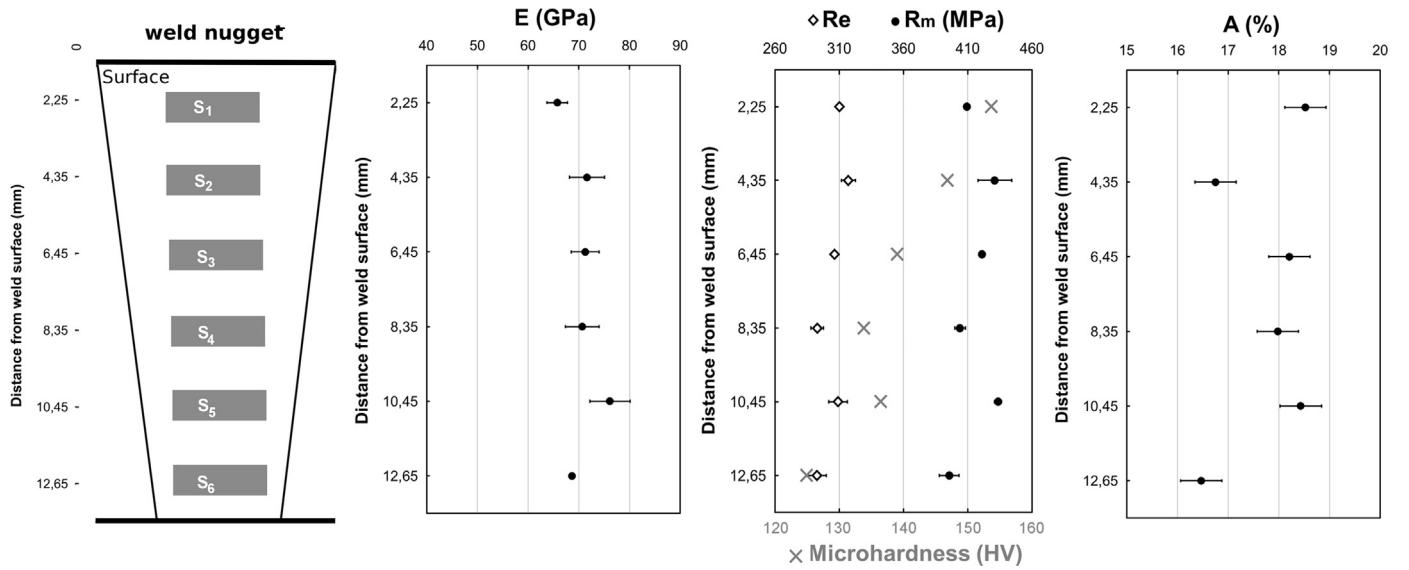

**Fig. 3.** EBSD map in the welding plane for a specimen machined from 7.8 mm below the top surface of the weld nugget and ODF (orientation distribution function) in the plane  $\phi_2=45^\circ$  for each texture band.

from 17  $\mu\text{m}$  to 4  $\mu\text{m}$  and the Hall-Petch rule saying that  $R_e$  scales  $d^{-1/2}$ ,  $R_{p0.2}$  should increase by about a factor 2 from S1 to S6. The fact that  $R_{p0.2}$  is constant means that the grain size effect is of the second order compared to the effect of the T1 density. This assumption is confirmed by the evolution of the hardness. The Vickers microhardness decreases from 155 Hv to 125 Hv though the grain size decreases from 17  $\mu\text{m}$  to 4  $\mu\text{m}$ . The opposite effect could be expected by applying the Hall-Petch type scaling to  $d^{-1/2}$  on Hv. This scaling is usually operant when  $R_e$  or  $R_m$  are proportional to Hv by a factor 2–4.  $R_m$  is about 3 times the average microhardness measured on the specimens S1–S6 but there is not a decrease of  $R_m$  with the microhardness and then no proportionality. The mechanical behavior of the nugget does not follow expected typical rules. The gradients of T1 density and grain size as well as the presence of textured bands make the mechanical behavior unusual. The specimens after failure are shown in Fig. 5. Though the fracture mode is ductile in all the cases, the fracture morphology is different depending on the sampling level in the nugget. On specimens S1–S3, the fracture occurs along a plane

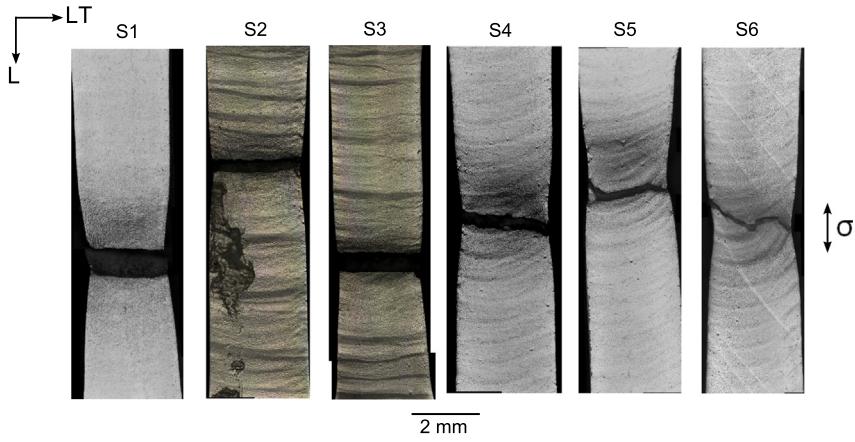

called  $P_1$  making an angle of about 45° with the tensile direction and the intersection with the  $L$ - $LT$  plane is parallel to the  $LT$  direction. A change of orientation of the fracture surface occurs progressively for the specimens S4–S6. Fracture occurs not only along the plane  $P_1$  but also along directions making an angle of about 45° on the  $L$ - $LT$  plane. For the specimen S6, the intersection between the fracture surface and the  $L$ - $LT$  plane is made of segments at 45° of the tensile direction. The reasons of these changes in the fracture morphology are not well understood. It can be only assumed that the T1 distribution and/or density may affect the shear orientation.

#### 4.2.2. Local strain heterogeneities in the $L$ - $LT$ plane

To quantify textured band-induced heterogeneity level of the strain field, analysis by DIC was done during all tensile tests. An example of axial strain field  $\epsilon_{11}$  is shown in Fig. 7 (specimen S4 at 7% deformation). The first observation is that the average axial deformation is always higher in the type A than in type B bands. It is to be noticed that, because of the plastic deformation of the

	$\epsilon_B - \epsilon_{\text{macro}}$	-0.25	-0.16	-0.25	-0.21	-0.42
	$\epsilon_A - \epsilon_B$	0.93	0.75	0.52	0.54	0.85
5	$\epsilon_A - \epsilon_{\text{macro}}$	1.13	1.05	0.55	0.65	0.83
	$\epsilon_B - \epsilon_{\text{macro}}$	-1.41	-1.33	-0.34	-0.38	-0.46
	$\epsilon_A - \epsilon_B$	2.54	2.38	0.89	1.03	1.29
7	$\epsilon_A - \epsilon_{\text{macro}}$	1.21	1.13	0.68	0.75	0.85
	$\epsilon_B - \epsilon_{\text{macro}}$	-1.69	-1.58	-0.42	-0.55	-0.62
	$\epsilon_A - \epsilon_B$	2.9	2.71	1.1	1.3	1.47

specimen, the strain field heterogeneity measured by DIC does not correspond exactly to the bands shown on the EBSD map (undeformed configuration). The second observation is that the strain field is not homogeneous in each band. This former point is not commented in detail here since it concerns a scale of the polycrystal beyond the purpose of this study. The focus is done on the average strain fields in each texture band. The values of the differences between the axial average strain in a band and the macroscopic strain, for each band type, each specimen (except S1 since it does not contain textured bands) and for different levels of macroscopic strain are given in **Table 1**. It should be remind here that the average strain in a textured band is the average value on all values at each ZOI belonging to the band, each value at a ZOI being the average value of the strain of a group of 10 grains. From **Table 1**, it is remarkable that in all cases, the strain of type A bands is higher than the macroscopic strain and then higher than the strain in type B bands. The second remarkable point is that the gaps  $\epsilon_A - \epsilon_B$  always decrease with the distance from the weld surface. In other words, the contrast in the strain field is higher close to the weld surface. This result may be crucial to account for in the context of possible damage resulting from the coupling between mechanical stress and corrosion process on the weld upper surface. The other characteristic point is that the gaps  $\epsilon_A - \epsilon_B$  increases with the macroscopic strain in all the cases. It means that the hardening is higher in band B than in Band A on all the range of macroscopic strain 1–7%. These results can be associated with some comments on the crystallographic features of the

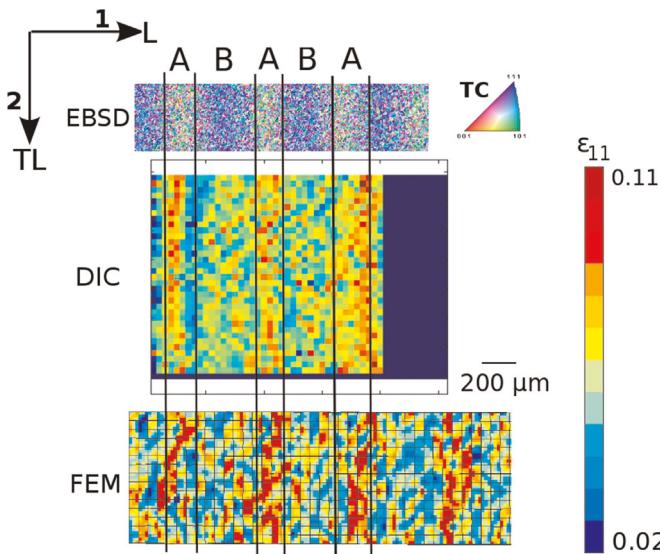

bands. From the EBSD analysis, Euler's angles of all the grains are obtained and the Schmid factor can be computed as  $\cos(\theta_s)\cos(\chi_s)$ , where  $\theta_s$  is the angle between the tensile axis and the primary slip direction, and  $\chi_s$  is the angle between the tensile axis and the normal of the primary slip plane. The average value of the Schmid factors of all the grains analyzed is 0.47 in type band A, and 0.45 in type band B. From the crystal orientation viewpoint and considering that slip is the deformation mechanism, the grains in type band A are deformed more than type band B by single slip. This is consistent with the results on the strain response of each band described previously. The crystallography data of the different bands were used to compute numerically the nugget by considering crystal plasticity model.

#### 4.3. Modeling of texture effect on mechanical fields heterogeneities

A finite element model was built to quantify the effect of the onion rings on the local strain heterogeneities. A part of the gauge length ( $2000 \times 750 \times 250 \mu\text{m}$ ) was modeled by a rectangular aggregate regularly meshed, where each element represented a grain. The element size of  $50 \mu\text{m}$  was chosen for numerical reasons. Two distinct domains, oriented to  $45^\circ$  in the depth, represent the two texture bands (A and B). For each texture band, a random selection of Euler's angles was chosen from the EBSD map and attributed to the Gauss points. The EBSD map constituted of 6000 grains was made on a S4 sample (see **Fig. 6a**). Boundary conditions are periodic displacements with an imposed stress of 430 MPa in

**Fig. 6.** (a) EBSD map of the gauge length, (b) mesh and domains used for fem computations, (c) axial strain map.

**Fig. 7.** Texture effect on local strain heterogeneities: results from DIC measurements and FEM computations after 7% global plastic strain.

the 1 direction (Fig. 6).

Fig. 6 shows the axial strain map ( $\epsilon_{11}$ ) obtained by FEM computations. The domains corresponding to A bands are more strained than others, as expected by the Schmid factors calculations (see Section 4.1.2). A good agreement is observed between the strain heterogeneities highlighted by finite element calculation and by DIC measurements, and the texture bands (see Fig. 7). In each band heterogeneity of strain field is observed and computed. For the finite element model, each element represents one grain, and the results show the strain heterogeneities due to the variation of crystallographic orientations between different grains of a same texture band. While for DIC, the measured local strain corresponds to a mean value on about 10 grains (corresponding to the zone of interest size).

Fig. 8 shows the tensile tests curves obtained by DIC method (Fig. 8a), and by finite element method (Fig. 8b). On each graph,

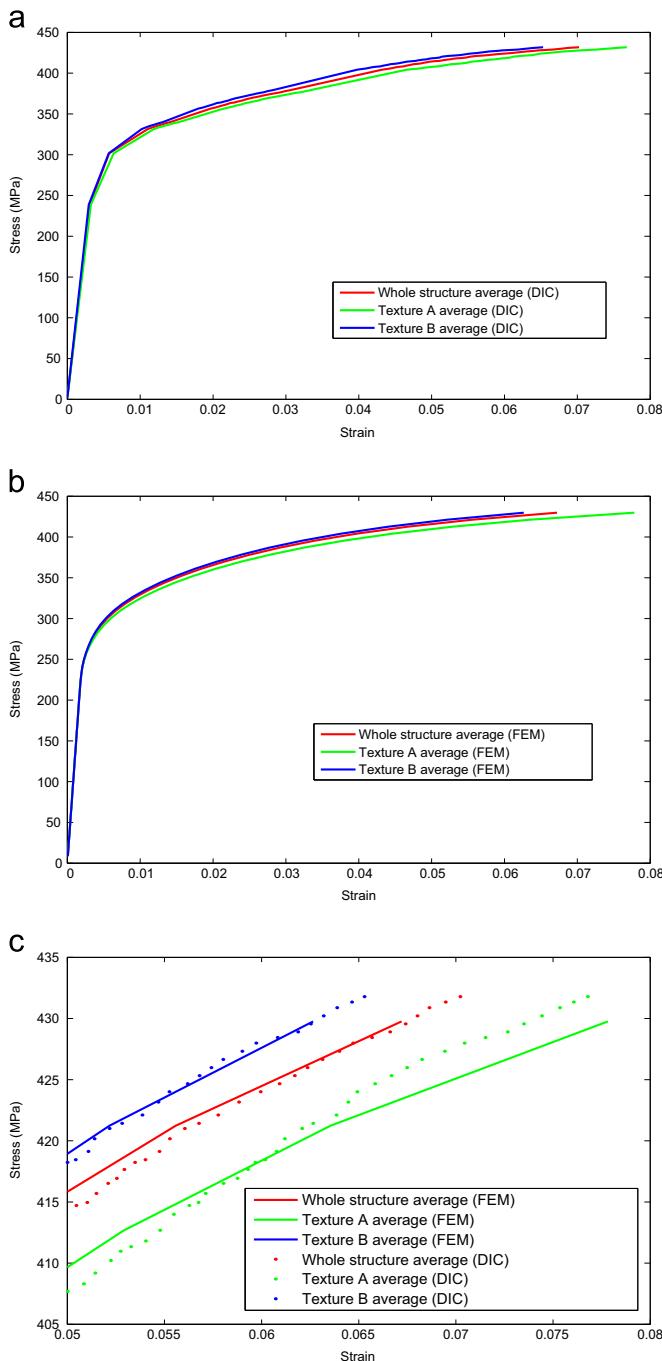

three curves are plotted:

- The red curve, called  $\epsilon_{11}^{total}$ , represents the average stress as a function of the average strain on the whole aggregate.
- The green curve, called  $\epsilon_{11}^A$ , represents the average stress as a function of the average strain on the A bands.
- The blue curve, called  $\epsilon_{11}^B$ , represents the average stress as a function of the average strain on the B bands.

The ends of the tensile curves were drawn in Fig. 8c. DIC curves in dashed line and FEM ones in plain line are almost superimposed. As texture bands cross the entire width of the sample, the specimen can be assumed as a Reuss problem, where the sample and both texture bands are submitted to the same stress. We can note that, for DIC curves and FEM curves the inequality  $\epsilon_{11}^A \geq \epsilon_{11}^{total} \geq \epsilon_{11}^B$  is clearly established whatever the macroscopic stress. For a macroscopic stress value of 430 MPa, the absolute variation between  $\epsilon_{11}^A$  and  $\epsilon_{11}^{total}$  is about 1% and the absolute variation between  $\epsilon_{11}^{total}$  and  $\epsilon_{11}^B$  is about 0.5%. Then, for the S4 level, the good correlation between EBSD map, DIC measurements and FEM results show that taking into account the crystallographic texture is sufficient to represent the mechanical behavior of the weld nugget. In the middle of the plate (from 7.8 mm below the top surface of the weld nugget), crystallographic orientations variation is mainly responsible for strain heterogeneities.

## 5. Concluding remarks

The mechanical behavior of the 2050 FSW weld nugget was characterized in the weld direction and at different distances to the weld surface. The periodic variation of crystallographic features on LT-ST surfaces of the tensile specimens forms bands of two types. These bands correspond to the sections of the FSW induced “onions rings” and lead to some uncommon strain response of the material. It was experimentally shown by in situ optic microscopy during tensile tests and digital image correlation that the type A bands undergo more deformation than the type B bands. Some general trends were quantitatively observed on the gap in the strain response between these two types of bands, and

**Fig. 8.** Tensile tests curves obtained by (a) DIC method, and by (b) finite element method. Red, green and blue curves represent the average stress as a function of the average strain on the whole aggregate, on the A bands, and on the B bands, respectively. (For interpretation of the references to color in this figure caption, the reader is referred to the web version of this paper.)

on the change of this gap with the distance to the upper surface of the weld. Crystal plasticity computations on a volume of material containing few textured bands simulate well the heterogeneity of the strain field. The mechanical behavior of each textured band was calculated. The strain gradient at the interface between the different types of bands is obviously produced probably some deleterious mechanical conditions favorable for example to the initiation and propagation of stress corrosion cracking [17]. The proposed mechanical analysis of the nugget of the weld is then very useful for estimating possible damage initiation and

propagation and more generally for assessing the durability of the welds by friction stir welding.
