## A B S T R A C T

Laser Assisted Machining (LAM) improves the machinability of materials by locally heating the workpiece just prior to cutting. Experimental investigations have confirmed that the cutting force can be decreased, by as much as 40%, for various materials. In order to understand the effect of the laser on chip formation and on the temperature fields in the different deformation zones, thermo-mechanical simulations were undertaken. A thermo-mechanical model for chip formation was also undertaken. Experimental tests for the orthogonal cutting of 42CrMo4 steel were used to validate the simulation. The temperature fields allow us to explain the reduction in the cutting force and the resulting residual stress fields in the workpiece.

## 1. Introduction

The use of high strength materials, like titanium alloys and tool steels, is becoming increasingly common in industry. However, these materials are difficult to machine because they maintain their mechanical properties even at high temperatures. Conventional machining of these materials is slow and inefficient, because only slow cutting speeds can be used. In order to increase productivity certain types of 'assistance' can be used to facilitate the cut, for example, high pressure ultrasonic assistance or assistance by locally heating, water jet assistance and cryogenic assistance, to name a few. The idea of hot machining began with the following processes: heating of the workpiece in a furnace, induction heating and/or electrical arc heating. But these processes did not give good results, because the power density was insufficient to be effective. In the sixties and seventies, electrical resistance heating between the tool and the workpiece was investigated. An electric current of several hundred amps made it possible to decrease the cutting force of approximately 10% in steels [1]. In the seventies and eighties, plasma heating was developed. An increase in tool life and productivity was noted [2]. Also in the eighties, CO<sub>2</sub> laser heating was tested, an improvement in the workability of several materials was noted. However, the cost of installing a CO<sub>2</sub> laser on a production scale is a significant barrier to the development of this process. Nowadays, because new, economic, easy and transportable laser sources, like diode lasers and Nd:YAG lasers are available, there is increased interest in Laser Assisted Machining (LAM).

LAM will only become viable on an industrial scale if it can be proved versatile in different domains of activity. It has already been shown that LAM makes it possible to machine high strength metals like Ti6Al4V [3,4], Inconel 718 [5], graphite iron [6], AISI D2 tool steel [7] or metal matrix composites [8] and ceramics [9–11]. For these materials, it improves workability by decreasing the cutting forces and by increasing the tool life. LAM is the only process with which it is possible to machine very hard materials. In addition, LAM can also increase the productivity when machining traditional or less hard materials. The cutting parameters (depth, speed, etc.) can be increased while improving the surface integrity of the part (surface quality, residual stresses). Moreover, machining is carried out dry, which allows cost reductions concerning the purchase and the treatment of lubricants and makes the process more environmental friendly. LAM can also increase the number of operations possible with the same machine. For example, a laser equipped lathe is able to carry out laser deburring and thermal surface treatments.

Optimization of the LAM process depends heavily on the control of laser heating. The laser heating must be extremely intense in order to affect the cutting process. But in this case, it can cause unwanted effects (thermal expansion of the workpiece, melting of the surface, etc). The goal of this paper is to propose a numerical approach to model laser assisted machining and highlight the effects of laser heating on the cutting zone.

### 1.1. Principle of LAM

LAM is a high temperature cutting process using a laser beam as the heat source (Fig. 1). The laser is used as an intense heat source to

Fig. 1. LAM configuration (for a turning operation).

Fig. 2. The Ultimate Tensile Strength ( $\sigma_{ULT}$ ) of various materials as a function of temperature [3].

decrease the strength of the machined material just prior the cut, without melting or sublimation of the workpiece.

The principle of the process is to reduce the cutting force necessary to machine the material by increasing the temperature to the point where the strength of the material is reduced (Fig. 2). Indeed at high temperature, the specific cutting energy is weak, which improves workability. Fig. 2 shows the characteristic evolution of the ultimate tensile strength of various materials with regard to temperature [3].

For a large number of materials a drop in the tensile strength or hardness occurs between 500 and 600 °C. To be effective the cutting tool must thus operate in the zone where the temperature remains higher than this value. However, the distance between the tool and the laser spot must be sufficient to prevent degradation of the tool due to the high temperature. A major feature of this process is the number of parameters that must be controlled during the cutting operation. In addition to the usual cutting parameters (cutting speed, feed rate, depth of cut and type of tool), there are the laser parameters (laser power, the angles of incidence and the diameter of the laser spot) and also interaction parameters between the laser beam and the cut (i.e. the position of the laser relative to the tool). The effect of the angle of incidence has been investigated by Germain et al. [12]. In particular, it has been shown that the laser beam absorption is the same for all angles of incidence less than 40° from the surface normal. The angle of incidence used for all of the work reported in this article is 20°. This

value was chosen in order to facilitate the tests (i.e. to prevent the laser nozzle from hitting the tool).

## 1.2. Experimental equipment

A numerically controlled lathe (REALMECA RT-5) equipped with a 2.5 kW Nd:YAG laser was used in this work. The laser nozzle can be controlled using three translations and two rotations. A Numerical Control System (NUM 1060) allows the control of the seven independent degrees of freedom. The high-power laser beam is delivered through a fiber optic cable to the lathe chamber, where it is focused on the workpiece surface. During machining, a gas under pressure (air) is forced through the laser nozzle to protect the focusing lens from being damaged by chips. Three components of the cutting force are measured by a Kistler piezoelectric dynamometer. The output signals for the cutting force are amplified and collected by a data acquisition system with the LabView® software.

## 1.3. Literature review of analytical solutions for the modelling of laser heating and LAM

As discussed by Chen [13] when considering only the laser heating, the temperature field can be determined by solving the heat equation. The analytical solution to calculate the temperature distribution in the workpiece resulting from a heat source with a Gaussian power distribution in motion has been reported by Chen. This equation developed is shown in Eq. (1). In this analytical model, the movement consists of a translation in the  $x$ -direction with a constant speed of  $V_x$ . The heat source is switched on at time,  $t=0$  and off at  $t=\tau$ . Heat transfer via radiation and convection are neglected. The laser beam is located at the origin at time  $t=0$  s. The thermo-physical properties ( $\alpha$  and  $k$ ) are assumed to be independent of temperature.

$$T(x,y,z,t) = T_0 + \frac{8P_a\sqrt{\alpha}}{k\pi^{3/2}} \int_{\sqrt{t-\tau}}^{\sqrt{t}} \frac{\exp\left[-4\frac{[x-V_x(t-u^2)]^2+y^2}{d^2+16\alpha u^2} - \frac{z^2}{4\alpha u^2}\right]}{d^2+16\alpha u^2} du \quad (1)$$

where  $T_0$  is the initial temperature,  $\alpha$  is the thermal diffusivity,  $P_a$  is the absorbed laser power,  $k$  is the coefficient of conduction,  $d$  is the diameter of the laser beam,  $V_x$  is the speed of the laser beam in the  $X$ -axis direction.

This solution is very general but it can be optimized for the LAM process. Analytical studies of laser heating in terms of LAM have been conducted at the University of Purdue by Rozzi et al. [14,15]. They determined the temperature field (3D) induced by a laser beam in a bar of silicon nitride in motion. Their model considers the laser beam moving in both axial and circumferential directions (Fig. 3). Natural and forced convection around the laser spot by the air stream used to protect the laser head are considered. The thermo-physical parameters of the workpiece are assumed to be independent of the temperature. Radiation is neglected.

The authors report that this model gives correct values for the temperature field. The temperature in the tool increases with the laser power and with the reduction of the laser beam diameter. Axial conduction in the workpiece is more important when the feed rate of the laser beam is low. The heated depth diminishes with increasing speed of rotation of the workpiece. In addition, the authors conclude that natural convection can be neglected. By contrast, the forced convection around the laser spot by the air stream must be considered.

This model has been further enriched by Rozzi et al. [16] to take into account the heat generated in the primary shear zone, the changing geometry of the workpiece during machining and

Fig. 3. Description of the analytical model developed by Rozzi et al. [15].

Fig. 4. Description of the enriched model developed by Rozzi et al. [16].

preheating of the material (Fig. 4). The results of this new model have been detailed for various process configurations [16].

In a further publication, Rossi et al. [17] note that heat generation in the primary cutting zone greatly increases the surface temperature at the location of the cut. This result brings into question the conclusion of their first model [14,15], which predicted a sharp drop in temperature with an increase in the rotational speed of the workpiece. Indeed, if the speed increases, the heat input due to the laser decreases, but the heat generated in the primary zone increases. With this in mind, the reduction in temperature at the tool as the rotating speed increases is much

lower than that obtained by their first model. However, the depth of the heated material is still lower at high speed.

This model was subsequently adapted by P.A. Rebro et al. for machining mullite [5] and by F. E. Pfefferkorn [9] for establishing a heat model of semi-transparent ceramics under LAM. The model helps to estimate the temperature with respect to the different process parameters, to optimize the power and to avoid cracks formation during the machining of ceramics. It provides an understanding of the phenomena, including the role of various parameters on the temperature field. However, in order to understand the role of heating on the various zones (i.e. the primary shear zone)

which are important in terms of chip formation the analytical approach of Rossi et al. is inadequate and an alternative approach must be studied. Hence, in this work, numerical modelling of LAM has been carried out using the finite element method to study the influence of laser heating of the material just prior to cutting.

## 2. Modelling procedure

The goal of this paper is to propose a numerical model, based on the finite element method, which is suitable for the study of LAM. This is necessary because the analytical models discussed above do not take into account the thermo-mechanical non-linearity's that occur in the cutting zone during chip formation. The LAM process simulation is conducted in two steps. Firstly, a purely thermal simulation of laser heating is undertaken and secondly a coupled thermomechanical simulation of the cutting process is completed. The temperature field resulting from the laser heating is the initial temperature field for the simulation of the cutting process.

### 2.1. Numerical model of the laser heating

In order to model the heat input due to the laser, a thermal flux was imposed on the workpiece over a zone corresponding to the surface of the laser spot. The thermal flux is displaced at the cutting speed and its intensity corresponds to the power absorbed by the material. During laser irradiation of the workpiece, only a small part of the laser beam energy is really absorbed by the material as the greater part is reflected. As a consequence the heat flux imposed in the numerical simulation as a loading condition must be the absorbed flux entering the part and not the total flux of the laser beam. The absorption coefficient represents the fraction of the absorbed power compared to the emitted power. This coefficient depends on many parameters such as the laser wavelength, the workpiece material, surface roughness, surface temperature, etc. The coefficient of absorption used in the simulation was determined by comparing numerical and experimental results.

To this end a numerical model was developed in order to determine the coefficient of absorption. This was done with the commercial finite element package Abaqus/Standard®. A fortran

subroutine was developed in order to apply and move the thermal flux along the top surface of the workpiece (Fig. 5), as a function of time. The laser beam was modelled as a surface heat flux with a Gaussian distribution and was applied over a surface whose diameter corresponds to the spot size (0.8 mm). The material properties necessary to resolve the problem include: the density, the thermal conductivity and the specific heat, all of which are dependent on temperature, in a range from 0 to 1150 °C. The latent heat of fusion has been introduced by artificially increasing the specific heat at the melting temperature of the material.

The finite element mesh was composed of 8-noded linear heat transfer bricks. A plane of symmetry was exploited so that, only half of the workpiece was modelled. The dimensions of the workpiece modelled were  $20 \times 2.5 \times 1 \text{ mm}^3$ . The initial temperature was 20 °C. The bottom face of the workpiece was maintained at 20 °C at all times. Numerical simulations were conducted with various laser powers and two laser displacement rates of 0.5 and 1  $\text{m s}^{-1}$ . These were the same as the experimental test which were carried out on a 42CrMo4 steel with seven laser powers (500, 750, 1000, 1250, 1500, 1750 and 2000 W) and two displacement rates (0.5 and 1  $\text{m s}^{-1}$ ). For each test the depth and the width of the molten zone were carefully measured. The absorption coefficient was determined by minimizing the differences between the simulated and the experimental molten pool volume (Fig. 6). The absorption coefficient was found to be effectively independent of the emitted laser power. Absorption coefficients of 0.26 and 0.27 were determined for displacement rates of 0.5 and 1  $\text{m s}^{-1}$ , respectively. Fig. 6 shows a relatively good correlation between the numerical and experimental results concerning the prediction of the volume of the melted zone.

The volume of the melted zone was chosen as a criterion for comparison because it reflects the energy absorbed by the material. However, the absorption of molten metal is different from that of the same non-molten metal, which creates an error when determining the absorption coefficient in this way. Never-the-less, this error is considered to be low because the tests discussed above result in a relatively small melted volume of material (i.e. the temperature is only slightly above the melting temperature).

The simulations appear to predict a molten volume with a slightly larger depth and a smaller width than the experimentally

Fig. 5. The temperature distribution resulting from laser heating (440 W at 0.5  $\text{m s}^{-1}$ ).

determined molten volume. Fig. 7 shows the 2D geometry of the calculated and experimental melted areas on the same scale, for a laser power of 1500 W and a displacement rate of  $0.5 \text{ m s}^{-1}$ . This difference is due to convection, conduction, Lorentz forces and surface tension (Marangoni flows) not taken into account in the numerical modelling. These phenomena induce movement in the melt which strongly influence the molten pool shape [18].

## 2.2. Thermo mechanical model of the cut

As discussed in Section 2 above, the second part of the numerical modelling procedure is to undertake a coupled thermo-mechanical simulation of the cutting process, using the temperature field resulting from the laser heating as the initial temperature field.

This was also done using the commercial finite element package Abaqus®. Two-dimensional models were built assuming conditions of plane strain. The dimensions of the workpiece were  $2.5 \times 1.6 \times 1 \text{ mm}^3$ . The workpiece was considered to be deformable and the lower face of the model was fixed (i.e. all displacements were set to zero). A temperature of  $20 \text{ }^\circ\text{C}$  was imposed on this face.

Fig. 6. Comparison between the experimentally and numerically determined molten volumes ( $0.5 \text{ m s}^{-1}$ ).

Neither free, nor forced convection at the workpiece surface was taken into account.

The plastic material behaviour of the 42CrMo4 steel was modelled using the temperature dependent Johnson-Cook law [19]. This behaviour law is a function of the temperature, the strain and the strain rate. The material properties used in the models are shown in Table 1.

The model was composed of predominately four node quadrilateral elements (CPE4RT) with coupled temperature-displacement degrees of freedom. Triangular elements (CPE3T) were also used on the lower part of the workpiece in order to increase the element size. The mesh contained 3272 elements. The approximate element size in the cutting zone is  $10 \text{ }\mu\text{m}$ . The tool was considered to be rigid with the same geometry as that used in the experimental work. The contact between the tool and the workpiece was modelled using a kinematic formulation with a constant Coulomb type friction coefficient of 0.1. The cutting speed was applied at the tool and the feed rate was considered to be negligible when compared to the cutting speed. A node separation criterion was not used to model the cut. In order to avoid premature distortion of the mesh an Arbitrary Lagrangian Eulerian formulation was applied to the elements of the workpiece. The formation of the chip occurs naturally via the rearrangement of the mesh. Re-meshing is not necessary in order to achieve the desired displacement.

## 2.3. Validation of the numerical model of the cut

The thermo-mechanical model has been validated by experimental orthogonal cutting tests. The tests are carried out on disks with a thickness,  $w$ , of  $1 \text{ mm}$  (Fig. 8).

The cutting tool consisted of a CFIR2525 M06 tool holder with LCGN 160202 0600FG CP500 inserts from SECO. Three different cutting speeds were investigated ( $V_c = 1, 2 \text{ and } 4 \text{ m s}^{-1}$ ) with a cutting depth (or feed) of  $a = 0.1 \text{ mm}$  for the 42CrMo<sub>4</sub> steel. For LAM, the laser power was fixed at  $1000 \text{ W}$  and the tool was placed  $3 \text{ mm}$  behind the laser beam. The calculated tangential cutting force was compared to the experimentally determined one. Fig. 9 shows the results for (a) Conventional Machining (CM) and (b) LAM

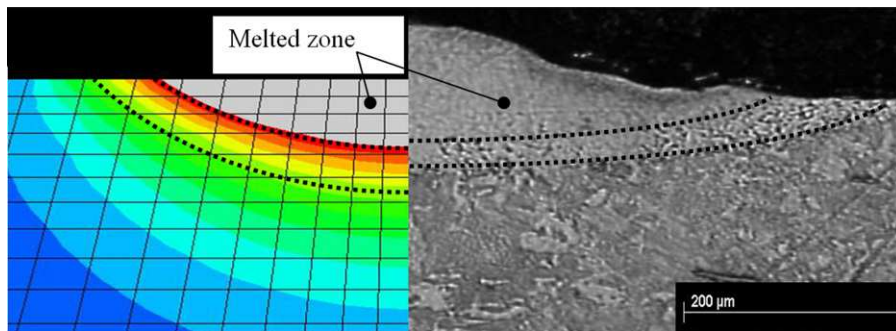

Fig. 7. Comparison between the geometry of the numerical and experimental thermally affected zone for a  $1500 \text{ W}$  laser power and a displacement rate of  $0.5 \text{ m s}^{-1}$ .

Fig. 8. Principle of orthogonal cutting.

Fig. 9. Comparison between the calculated and experimentally determined tangential cutting forces for different cutting conditions: (a) conventional machining and (b) LAM.

as a function of the cutting speed. It can be seen that the numerical predictions are good. Laser assistance results in a reduction of the cutting force by 34%, 21% and 10%, respectively, compared to conventional machining for the three cutting speeds investigated.

The chips obtained experimentally via orthogonal cutting are continuous and correspond in general to the chip form generated via the numerical simulation. The good agreement between the experimental and numerical values validates the numerical model of the LAM process, at least for the cutting configuration studied (orthogonal cutting, steel 42CrMo<sub>4</sub>,  $a=0.1$  mm and  $1 < V_c < 4$  m s<sup>-1</sup>).

### 3. Influence of the cutting speed in LAM on the temperature field

The maximum calculated temperatures at the laser spot are approximately 1346, 954 and 680 °C for cutting speeds of 1, 2 and 4 m s<sup>-1</sup>, respectively. The affected depth also decreases similarly with the cutting speed. The temperature profiles in the vicinity of the cutting tool (i.e. 3 mm behind the laser spot) are shown in Fig. 10 for the three cutting speeds. It can be seen that the average temperatures in the layer of material removed are 377, 259 and 171 °C for the different cutting speeds. These temperatures cause a decrease in the cutting force of 34%, 21% and 10% with respect to conventional machining. This observation joins the results of the Shvarenina et al. which show a significant fall in temperature between the impact of the laser and the cutting tool [5].

The depth of the heated zone is greater than the cutting depth (i.e. 0.1 mm in Fig. 10). Therefore, some of the thermal energy provided by the laser is removed by machining. This heat energy which causes a global increase in the temperature of the workpiece, results in unwanted thermal expansion. This was observed experimentally.

#### 3.1. Comments on chip formation in LAM

Differences, in terms of the temperature, stress and strain fields, can be observed when comparing the numerical simulation of conventional cutting and the simulation of LAM. Hence, various comments can be made concerning chip formation in LAM. Below, two simulations are compared with a cutting speed of 1 m/s and a cutting depth of 0.1 mm, with and without laser assistance of 1000 W.

#### 3.2. Comparison of the primary shear zones

The results show that the shear angle in the primary shear zone is approximately 35° for conventional turning and only 21° for LAM. This confirms the results of Lesourd [3] who stated that the shear angle decreases with an increase in the initial temperature of the workpiece. However, the decrease of the shear angle has the consequence of increasing the length of the primary shear zone and of increasing the thickness of the chip (Fig. 11).

The initial temperature, at the beginning of the primary shear zone is 20 °C in the conventional turning case and approximately 380 °C for the LAM case. The large plastic deformation in this zone increases these temperature values to 300 and 600 °C, respectively. Hence, the increase in temperature in the primary shear zone is more important in conventional machining than in LAM (respectively, 280 and 220 °C).

Also, by comparing the thermal flux generated by the primary zone (i.e. self-heating) with and without laser assistance, the flux in conventional cutting is seen to be more significant. The average

thermal flux in conventional turning is approximately  $2.4 \times 10^8 \text{ Wm}^3$  and only  $1.7 \times 10^8 \text{ Wm}^3$  in LAM (Fig. 12). This can be explained by the fact that the increase of temperature via the laser input results in a decrease in the flow stress which in turn causes less self-heating of the material during the plastic deformation.

Fig. 10. Temperature profiles at the cutting tool for different cutting speeds.

### 3.3. Comparison of the secondary shear zone (chip/tool)

The chip temperature is strongly influenced by the friction between the tool and chip. The temperature at the tool/chip contact surfaces is calculated to be approximately 600 °C in conventional machining and 800 °C in LAM.

The heat generated by friction is proportional to the shear stress multiplied by the slip speed. The contact shear stress at the tool/chip interface is approximately 100 MPa in conventional machining and 77 MPa in LAM. Also, the slip speed is slower in LAM due to the decrease of the shear stress angle. The slip speeds between the chip and tool have been calculated to be approximately  $1.16 \text{ m s}^{-1}$  in conventional machining and approximately  $1.12 \text{ m s}^{-1}$  in LAM. Hence, as the flow stress and the slip speed are lower in LAM, there is less heat generated. This is a positive point in favour of LAM, because an increase in temperature of approximately 400 °C of the workpiece causes only an increase of 200 °C at the tool (Fig. 11). The tool is less mechanically loaded in LAM as the stress at the contact surface between the tool and the workpiece remains low.

Fig. 11. Calculated temperature distribution (a) without and (b) with laser assistance.

Fig. 12. Thermal flux distribution generated by the primary shear zone (a) without and (b) with laser assistance.

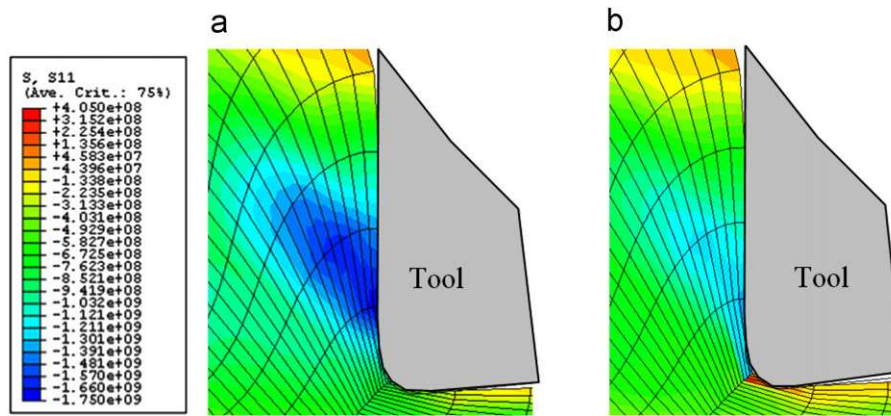

Fig. 13. Stress field in the secondary shear zone (a) without and (b) with laser assistance.

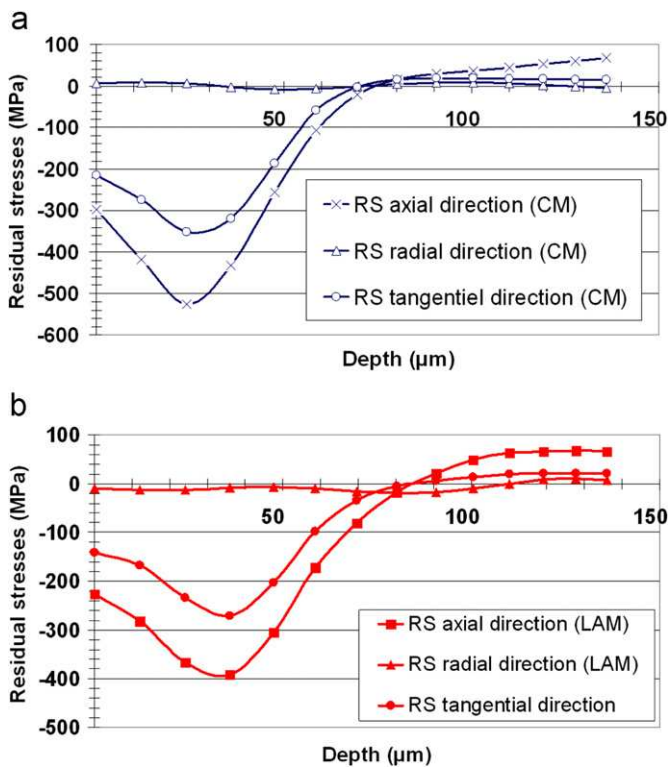

Fig. 14. Residual stress profiles for (a) conventional machining and (b) LAM.

In conventional machining on the other hand, there exists a strong compressive stress field ( $-1750$  MPa) normal to the contact surface between the tool and the workpiece. This zone also exists in LAM, however, the stress values are less important ( $-1300$  MPa). The compressive zone of the chip on the tool is situated behind the cutting edge (Fig. 13). Lower stress in this zone could explain the decrease of the cutting force measured in LAM.

### 3.4. Comparison of the tertiary zone (workpiece/tool)

Even though the tertiary shear zone is smaller in size, it has a strong influence on the surface integrity of the workpiece and in particular on the creation of residual stresses. Via the numerical simulations it was possible to calculate the depth of the zone affected by residual stresses and the residual stress profiles. The

calculated profiles are in agreement with the experimentally determined profiles generally obtained in machining. Indeed, machining induces a residual stress profile that can be divided into three zones:

- A sharp increase in compressive residual stress within several tens of micrometers to a minimum value.
- Followed by a sharp increase of residual stress within several tens of micrometers up to the values of initial stress of the material.
- Then in order that the residual stress field is self-equilibrated, the stress slowly increases to a value slightly above the initial stress.

The results indicate that LAM causes lower compressive residual stress at the machined surface. A difference of  $100$ – $150$  MPa is observed between the numerically determined stress profiles in (a) conventional machining and (b) LAM (Fig. 14). This evolution of residual stresses is in accordance with experimental results observed in conventional and laser assisted machining on a titanium alloy [4].

## 4. Conclusion

Numerical simulations of conventional turning and LAM have been undertaken and validated against experimental tests. These experimental tests consisted of orthogonal turning of  $42\text{CrMo}_4$  steel. Three cutting speeds were investigated ( $1$ ,  $2$  and  $4$   $\text{m s}^{-1}$ ) with a constant feed of  $0.1$   $\text{mm}\cdot\text{rev}^{-1}$ . Each test was undertaken without laser assistance (Conventional Machining or CM) and with a laser assistance of  $1000$  W.

The results show that:

- (1) The numerical prediction of the tangential component of the cutting force is very good, with errors of less than  $2\%$  for CM and less than  $8\%$  for LAM compared to experimental tests.
- (2) A reduction of the cutting force with laser assistance that is more pronounced with lower cutting speeds. The experimental tests showed a decrease in the cutting force in LAM with respect to CM of  $34\%$ ,  $21\%$  and  $10\%$ , for the 3 cutting speeds.
- (3) A decrease in the heated depth and a decrease of the surface temperature with an increase in cutting speed. Indeed, the average temperature just in front of the cutting tool in the material being removed, for the 3 cutting speeds are  $377$ ,  $259$  and  $171$   $^{\circ}\text{C}$ .

Comparison of chip formation in the numerical analysis was also undertaken in both LAM and CM. This was done for simulations with a cutting speed of  $1 \text{ m s}^{-1}$  and a feed of  $0.1 \text{ mm.rev}^{-1}$ .

The results show that:

- (1) In LAM the average temperature in the primary shear zone (ZI) is approximately  $400 \text{ }^\circ\text{C}$  higher than the corresponding temperature in CM. Also, the stresses in the zone ZI are lower in LAM ( $\sim 1100 \text{ MPa}$ ) than in CM ( $\sim 1700 \text{ MPa}$ ). This implies that in LAM the self-heating, due to the deformation, is less important in this zone, when compared to CM. The temperature difference between LAM and CM at the exit of the primary shear zone is less than  $300 \text{ }^\circ\text{C}$ .
- (2) In the secondary shear zone (ZII) at the tool/chip interface, in LAM less heat is produced via friction between the tool and the chip. The temperature difference at the cutting face of the tool is not greater than  $200 \text{ }^\circ\text{C}$ . Less heat is generated in LAM because the shear stresses in the zone (ZII) are lower. Furthermore, the slip speed at the chip/tool interface is slower. The reason is that in LAM the shear angle in the Z1 zone decreases. This increases the thickness of the chip and therefore decreases its sliding velocity. Moreover, the high compressive stresses located at the ZII zone are more important in CM ( $\sim 1700 \text{ MPa}$ ) compared to LAM ( $\sim 1100 \text{ MPa}$ ).

To validate the thermal aspects of the numerical simulations, a new acquisition system is currently being developed to measure the temperature field. A near infra-red camera, directly fixed on the laser head support, will make it possible to analyze the thermal fields during a machining operation. With this set-up it will be possible to validate the thermal aspects of the numerical simulations in addition to the mechanical aspect. This acquisition system was developed by M'Saoubi [20] for conventional machining and it has recently enabled us to study the machining temperatures for treated bearing steel 100Cr6 at 55 HRC [21].
