As two fluid particles separate in time, the entire spectrum of eddy motions is being sampled from the smallest to the largest scales. In large-scale geophysical systems for which the Earth rotation is important, it has been conjectured that the relative diffusivity should vary respectively as D^2 and $D^{4/3}$ for distances respectively smaller and larger than a well-defined forcing scale of the order of the internal Rossby radius (with D the r.m.s. separation distance). Particle paths data from a mid-latitude float experiment in the central part of the North Atlantic appear to support these statements partly: two particles initially separated by a few km within two distinct clusters west and east of the mid-Atlantic ridge, statistically dispersed following a Richardson regime ($D^2 \sim t^3$ asymptotically) for r.m.s. separation distances between 40 and 300 km, in agreement with a $D^{4/3}$ law. At early times, and for smaller separation distances, an exponential growth, in agreement with a D^2 law, was briefly observed but only for the eastern cluster (with an e-folding time around 6 days). After a few months or separation distances greater than 300 km, the relative dispersion slowed down naturally to the Taylor absolute dispersion regime.

1. Introduction

Observations of the separation of pairs of particles is one of the few experimental methods available to examine the spatial structure of geophysical turbulent flows. Richardson (1926) proposed that the relative diffusivity of an ensemble of pairs should scale as the $4/3$ power of the (r.m.s.) separation distance. In his review of the subject, Corrsin (1962) emphasized the concept that turbulent eddies much smaller or much larger than the separation scale are relatively inefficient in further separation at the difference of eddies near the separation scale: the small eddies cause independent random walks of each member of the pair while the larger ones move the pair coherently as a single unit. As a result the relative velocity of the pair changes with the separation and is a non-stationary random variable. This accelerating property of relative diffusion has been used to infer properties of the energy wavenumber spectrum in the inertial range. The key quantity in the inertial range of three-dimensional turbulence is the energy dissipation rate. When the relative diffusivity is assumed to depend only on this energy dissipation rate and on separation, Richardson's law is recovered (Obukhov 1941; Batchelor 1952). The study of particle dispersion is important because of the interest in transport and mixing of chemicals in large-scale geophysical systems. While Taylor's (1921) single-particle dispersion theory relates to tracer dispersal from a fixed geographical origin and for very large times, two-particle dispersion relates to the spreading of a cloud of tracer from its centre of gravity (Batchelor 1952) and will

give information on the cloud size growth as time increases. Relative dispersion thus describes the fate of a passive tracer much better than one-particle dispersion.

The subject has now branched into two, with the dispersive effects of three-dimensional high Reynolds number turbulence on the one hand and those of two-dimensional turbulence on the other. The former has been recently reviewed (Sawford 2001). Because the oceanic motions that separate the floats in our experiment are associated with a small Rossby number (horizontal characteristic length scale L greater than 1 km), the latter context seems more appropriate, although it is only under certain circumstances (to be detailed below) that the flow can be considered approximately two-dimensional. In two-dimensional free turbulence, the square of relative vorticity is conserved following fluid particles and enstrophy (or mean square relative vorticity) cascades to small scales while energy moves up scale as a result of nonlinear interactions (Batchelor 1953). Similarly, Kraichnan (1967) showed that two-dimensional forced turbulence admits two formal inertial ranges, one on each side of a given injection scale, with an inverse energy cascade at scales larger than the injection scale and a direct enstrophy cascade at smaller scales. He then proposed that the same arguments used in the three-dimensional case to infer the $4/3$ law could be applied to the region of the inverse energy cascade, an idea which has been supported by various turbulence closure calculations (Kraichnan 1966; Larcheveque & Lesieur 1981).

In the inertial range of the enstrophy cascade, Lin (1972) proposed that relative dispersion should depend only on the separation and on the enstrophy dissipation rate with the consequence that at such scales the relative diffusivity varies as the square of the separation. This in turn implies that the mean-square separation grows exponentially in time. Kraichnan & Montgomery (1980) note in their review of two-dimensional turbulence that separation is then smaller than the size of the eddies that carry most of the shear. This approximates the situation of spatially uniform random shear with the rate of separation proportional to the separation. Larcheveque & Lesieur (1981) confirmed the validity of this regime under an eddy damped quasi-normal Markovian (EDQNM) closure. Numerical experiments in the framework of two-dimensional homogeneous decaying turbulence carried out by Kowalsky & Peskin (1981), did show a short exponential regime (with a ratio of the initial r.m.s. separation to the injection scale of 0.035). However, Babiano *et al.* (1990) who conducted similar numerical experiments, following Kraichnan's assumptions of forcing at a well-defined wavenumber, observed that the exponential law was "reduced to a very short transient stage". On the other hand they found that the t^3 asymptotic law, a consequence of Richardson's law, was obtained "provided the initial separation of the particles is smaller by an order of magnitude than the injection scale", a condition which looks surprising and will be discussed below. An experimental study of the dispersion of pairs of passive particles in a stratification controlled two-dimensional laboratory flow was performed recently by Jullien, Paret & Tabeling (1999), the local forcing being provided by the interaction of an electrical current with a magnetic field. Within the inertial range of the inverse cascade (i.e. at scales larger than the forcing scale), the t^3 law was observed along with a strongly non-Gaussian behaviour for the probability distribution of pair separations (with initial separations much smaller than the injection scale).

The application of these two-dimensional physical concepts to large-scale geophysical rotating and stratified flows (e.g. in the ocean or atmosphere) has no definite results yet (see the reviews by Rhines 1979, and Salmon 1998). If the flow time scale is much greater than f^{-1} , and the flow horizontal length scale L much smaller than $f\beta^{-1}$ ($f = 2\Omega \sin \varphi$ and $\beta = df/a d\varphi$, with Ω the Earth rotation rate, φ the latitude

and a the Earth radius), then with an horizontal velocity scale U much smaller than fL (Rossby number $\ll 1$), quasi-geostrophic potential vorticity is conserved along a quasi-horizontal trajectory (e.g. Gill 1982). If furthermore L is much smaller than the internal Rossby radius of deformation R_{int} (at which vortex stretching appears) and the Rhines scale $(U/\beta)^{1/2}$ (at which planetary waves start to propagate), the flow is effectively quasi-two-dimensional. Since $R_{int} \sim 30$ km while $(U/\beta)^{1/2} \sim 70$ km at mid-latitudes in the ocean, such a quasi-two-dimensional regime is possible and could be observed near scales of the order of a few km ($U \sim 0.01$ m s⁻¹ to 0.1 m s⁻¹). In the ocean and atmosphere the energy source for the meso- (or synoptic) scale eddies comes mainly, through baroclinic instability, from the potential energy associated with the sloping isopycnals of the semi-permanent jets (Gill 1982). Eddy kinetic energy is injected preferentially at the scale (scale being defined as wavelength/ 2π) of the internal Rossby radius of deformation R_{int} which would thus play the role of Kraichnan's injection scale. However, in the atmosphere, the range of horizontal scales over which the quasi-two-dimensional regime could exist may be narrower than in the ocean, since atmospheric values for R_{int} and $(U/\beta)^{1/2}$ are both of the order of 700 km while the condition of a small Rossby number imposes scales greater than 100 km, for speed of ~ 1 m s⁻¹.

Discarding the β effect (thus for horizontal scales much smaller than the Rhines scale), but keeping the vertical stretching term in the quasi-geostrophic potential vorticity, Charney (1971) has shown that for scales smaller (not necessarily much smaller) than R_{int} , a potential enstrophy inertial range can exist under certain conditions, which renders Lin's law for pair dispersion still plausible with potential enstrophy dissipation rate as the leading controlling parameter.

At scales larger than R_{int} , and for uniform stratification, Rhines (1979) has argued that an inverse energy cascade is still possible in the horizontal and vertical directions, the cascade proceeding to a state of alternating, weakly interacting barotropic (i.e. z -independent) zonal jets of width $O(U/\beta)^{1/2}$. There is no observational evidence that the oceanic eddies equilibrate similarly. Stammer (1997) has shown that eddies at the surface scale with R_{int} and not with $(U/\beta)^{1/2}$ while equipartition of the first baroclinic mode and barotropic mode energy is usually observed at mid-latitudes (Wunsch 1997). On the modelling side small-scale topography (Tréguier & Hua 1988) or realistic oceanic stratification (Smith & Vallis 2001, 2002) have been shown to be serious candidates to prevent the inverse cascade reaching a full barotropic state. The applicability of the Richardson–Kraichnan law to realistic regimes of oceanic turbulence (beyond the two-dimensional hypothesis) thus remains open giving added value to any experimental evidence that might be gained on such an issue.

The EOLE experiment was the first geophysical experiment aimed at testing these laws of two-dimensional relative dispersion in the mid-latitude atmosphere and Morel & Larcheveque (1974) observed the initial exponential time regime of the enstrophy cascade. In the TWERL experiment, Er El & Peskin (1981) confirmed this exponential regime but the demonstration of a Richardson regime at larger scale proved elusive. These authors emphasized the importance of looking at the dispersion in the time domain, a proposal that we share: we will show the differences that arise when averages of pair diffusivity are constructed as a function of distance or time. Assuming that the strain rate separating a pair was dominated by eddy scales near the separation distance, Morel & Larcheveque (1974) concluded that the D^2 law for the relative diffusivity was evidence of the existence of a k^{-3} energy spectrum in the enstrophy inertial range. This conclusion was disputed by Bennett (1984) and Babiano, Basdevant & Sadourny (1985) who argued that such a diffusivity law implies only

that the slope of the energy spectrum is steeper than or equal to -3 . When the slope is steeper than -3 , the separation process is said to be non-local meaning that eddies of scales larger than the separation also contribute to the diffusivity. Bennett (1984) describes the two effects: local straining causing a blob of contaminant to become highly convoluted with significant cross-diffusion before the blob envelope reaches the scale of the energy-containing eddies and non-local straining causing the blob to be drawn into a few long streaks with little cross-diffusion.

Summarizing the oceanic experimental context some thirty years ago, Okubo (1971) found that the $D^{4/3}$ law for the relative diffusivity along with the t^3 law for the mean-square separation held for a range of scales from 10 m to 300 km, the fit being local in the sense that the proportionality constant, the energy dissipation rate, had to be varied to accommodate this large spectral breadth. Most of the data in Okubo's diffusion diagrams came from surface dye releases in coastal areas where processes as varied as wind waves, tidal and inertial fluctuations are present. As Okubo points out, the similarity theory of turbulence is one possibility among others to rationalize the data (but he did not say whether he meant the two- or three-dimensional version of that theory). He & Bennett (1987) drew attention to the combination of mean shear and turbulent mixing as another possible cause for the t^3 law.

Although float observations have become common practice to infer the large-scale oceanic circulation, investigations of turbulent dispersion revealed by the floats have concerned for the most part one-particle (or so-called absolute) dispersion. McWilliams *et al.* (1983) showed an example (calculated by Price) from the Local Dynamics Experiment (LDE), with floats at depth of 700 m approximately, in the North West Atlantic ($\sim 31^\circ\text{N}$, $\sim 70^\circ\text{W}$), supporting a $D^{4/3}$ law for separation distances between 70 and 300 km, and suggesting a D^2 law for smaller separations. Recently Lacasce & Bower (2000) computed relative dispersion from four mid-latitude float experiments (including LDE) in the North Atlantic for three classes of initial separations ($D_0 \leq 7.5$ km, ≤ 15 km and ≤ 30 km respectively): relative dispersion in the two Western sites was shown to follow roughly a $4/3$ law for r.m.s. separations in the 10–100 km range, but exponential stretching was not resolved. For the two other regions (ACCE and AMUSE experiments), relative dispersion varied linearly with separation instead, a result interpreted by the authors to be the signature of a stochastic mixing process with particles essentially uncorrelated in space. Finally, using 25 day trajectories from surface drifters deployed in the Gulf of Mexico, Lacasce & Ohlmann (2003) obtained, for small initial separations ($D_0 \leq 1$ km) an exponential growth over the time range 2 to 10 days after launch, corresponding to separation distances between 5 and 40 km.

The TOPOGULF experiment whose data is used in the present paper was carried out in the central interior of the subtropical gyre of the North Atlantic away from boundary currents. Acoustically tracked subsurface floats were deployed at 700 m depth in the main thermocline (Ollitrault & Colin de Verdière 2002a) at scales sufficiently small initially to allow tests of the various laws of relative dispersion against distance or time chosen as independent variables respectively. More specifically this data set should allow the following questions to be answered:

Is there evidence of an exponential regime of relative dispersion?

Is there evidence of a transition to a Richardson regime before the members of a given pair randomly walk independently?

Section 2 describes briefly the float experiment. The theoretical elements needed are presented in §3. Section 4 and §5 describe respectively the statistical treatment of the data and the results. These results are further interpreted in §6.

2. The float experiment

As part of the TOPOGULF experiment (Arhan, Colin de Verdière & Mercier 1989; Colin de Verdière, Mercier & Arhan 1989), 26 quasi-Lagrangian subsurface (SOFAR) floats were used to track water particles near 700 dbar in the mid-latitude North Atlantic, over a 6 year (mid 1983 to mid 1989) period. Fifty three float years were collected, allowing absolute velocities and displacements for intermediate water particles from submesoscales (i.e. with characteristic length and time scales of order 10 km and 5 days) to mesoscales (100 km and 50 days) up to the largest scales of the circulation (in the present experiment roughly 1000 km and 500 days) to be obtained. Fourteen floats were launched (4–7 July 1983) within a 75 km diameter circle centred 36°N 40°W, west of the Mid-Atlantic Ridge (MAR), with a near neighbour distance of 18 km. Ten floats were launched one year later (28–29 October 1984) within a 45 km diameter circle centred 33°N 33°W, east of the MAR, as two duos and two trios (two or three floats separated by 2 km), with 18 km distance between groups. However only one trio and one duo (plus two single floats) will be used in this study since three floats equilibrated deeper than 1100 dbar after launch. Two of these three rose back into the [600, 800] dbar interval but much too late to be useful here. Three more floats (one duo and a single float) were released on 11 September 1985 in the same region.

Float trajectories have revealed a very turbulent circulation of the subtropical Atlantic (30°N to 45°N) and an influence of the mid-Atlantic ridge (MAR) on the large-scale motions. Trajectories, mean circulation and one-particle dispersion can be found in Ollitrault & Colin de Verdière (2002*a, b*) referred to as OCV from here on.

In the present context of estimating the rate of dispersion of float pairs, it is important to discuss position errors of the floats. Our SOFAR floats were positioned every 12 h, with an accuracy of a few km. Errors on positions are due to several causes, the most important ones being:

- (i) Imperfect knowledge of the speed of sound used to convert times into distances, which are used through least-square minimization to estimate the float position.
- (ii) Error in estimating the times of propagation because of the poor knowledge of the float and listening station clock drifts.
- (iii) 'Bad' geometry for the least-square fit (e.g. for a float positioned well away from a cluster of listening stations, so that constant times of propagation loci intersect each other at very small angles, or even never intersect).
- (iv) Imperfect separation by the listening station correlator of the different sound rays received (from a float).

For the purpose of our study however, which is to calculate the time rate of change of separation and relative velocity vectors between two given floats for separation distances less than a few hundred km, systematic errors should cancel out approximately. To reduce any random (as opposed to systematic) errors, a low-passed filter was applied to the raw position time series to cut off periods less than ~ 3 days and velocities were estimated with a cubic spline fitted to the filtered positions (Ollitrault 1994). This procedure is thought to provide an accuracy of a few hundred metres for the separation vector when floats are less than a few tens of km apart, degrading to probably 1 km or more as separation increases to a few hundreds of km. Instantaneous velocities are assumed accurate to within 1 cm s^{-1} .

3. Theoretical considerations

Following Richardson's (1926) result for three-dimensional turbulence, Kraichnan (1966, 1967) proposed the following law for the relative diffusivity of pairs as function

of the r.m.s. separation distance in the inverse cascade regime of two-dimensional turbulence:

$$\frac{1}{2} \frac{dD^2}{dt} \sim \varepsilon^{1/3} D^{4/3} \quad \text{for } D \gg D_I$$

where D_I is a forcing injection scale and ε is the energy flux to larger scales. A similar argument led Lin (1972) to propose for the inertial range associated with the enstrophy cascade of two-dimensional turbulence:

$$\frac{1}{2} \frac{dD^2}{dt} \sim \chi^{1/3} D^2 \quad \text{for } D \ll D_I$$

where χ is the enstrophy dissipation rate (see Kraichnan & Montgomery 1980 and Lesieur 1997 for a review of the underlying concepts). Both laws are proposed up to a dimensionless constant which can only be estimated from dispersion measurements supplemented by direct estimation of the dissipation rates themselves (Larcheveque 1983). It is readily seen that, after integration, Kraichnan–Richardson’s law gives

$$D^2 = (D_0^{2/3} + \frac{2}{3} c \varepsilon^{1/3} t)^3 \quad (1)$$

while Lin’s law implies exponential growth:

$$D^2 = D_0^2 \exp(2d \chi^{1/3} t)$$

where c and d are the aforementioned non-dimensional constants and D_0 is the initial separation distance.

Following Babiano *et al.*’s (1990) presentation, the single-particle Taylor’s (1921) formulation applied to the relative dispersion proceeds as follows:

$$D^2(t, D_0) = \langle D^2(t, D_0) \rangle = \langle \mathbf{D}(t, D_0) \cdot \mathbf{D}(t, D_0) \rangle$$

is the mean-square separation distance at time t . Here \mathbf{D} is the separation vector of a pair of particles (named a and b), and $\langle \cdot \rangle$ denotes the ensemble average at time t over all particle pairs initially separated by a given distance $D_0 = \|\mathbf{D}_0\|$. If $\delta \mathbf{V} = (d/dt)\mathbf{D} = \mathbf{V}_a - \mathbf{V}_b$ is the Lagrangian relative velocity vector for the same pair of particles a and b, then

$$\mathbf{D}(t, D_0) = \mathbf{D}_0 + \int_0^t \delta \mathbf{V}(\tau, D_0) d\tau.$$

The relative diffusivity can now be rewritten as

$$\begin{aligned} Y(t, D_0) &= \frac{1}{2} \frac{d}{dt} \langle D^2(t, D_0) \rangle = \langle \mathbf{D}(t, D_0) \cdot \delta \mathbf{V}(t, D_0) \rangle \\ &= \langle \mathbf{D}_0 \cdot \delta \mathbf{V}(t, D_0) \rangle + \int_0^t \langle \delta \mathbf{V}(t, D_0) \cdot \delta \mathbf{V}(\tau, D_0) \rangle d\tau. \end{aligned} \quad (2)$$

Relative velocities are not stationary random variables because the covariances in (2) keep their dependence on pair separation D_0 and on time after release. Using the definition of $\delta \mathbf{V}$ in terms of absolute velocities \mathbf{V} , the last term in (2) can be rewritten as

$$2K(t) - 2 \int_0^t \langle \mathbf{V}_a(t) \cdot \mathbf{V}_b(\tau) \rangle d\tau.$$

$K(t)$ is the single-particle absolute diffusivity (actually K is the trace of the diffusivity tensor i.e. the sum of individual diffusivities in two orthogonal directions). For large time or large initial separation compared to the energy-containing scale, the two

members of the pair wander independently and the last term above vanishes in which case the relative diffusivity becomes just twice the single-particle absolute diffusivity provided that the covariance $\langle D_0 \cdot \delta V(t, D_0) \rangle$ also vanishes. This is clearly the case at the initial time, after ensemble averaging over a very large number of particle pairs placed randomly in homogeneous turbulence (Davis 1985) but also (less obviously) for later times as verified numerically by Babiano *et al.* (1990). However, this is unlikely in geophysical experiments (because too small a number of pairs is available). In the absence of this term, Babiano *et al.* (1990) have shown on pure kinematical grounds that when t goes to zero (that is when the relative velocities are perfectly correlated), the relative diffusivity and the relative dispersion grow in time respectively as t and $D_0^2 + \langle \|\delta V_0\|^2 \rangle t^2 = D_0^2(1 + Zt^2)$, where Z is the enstrophy given by $\frac{1}{2} \langle \|\text{curl} V\|^2 \rangle_x$ (spatial averaging carried out over the entire domain is denoted by $\langle \cdot \rangle_x$).

The mean-square relative velocity is also a quantity that can be estimated from observations. From its definition we have

$$\left\langle \frac{dD}{dt} \cdot \frac{dD}{dt} \right\rangle = \langle \|\delta V(t, D_0)\|^2 \rangle = \langle \|\mathbf{V}_a(t)\|^2 \rangle + \langle \|\mathbf{V}_b(t)\|^2 \rangle - 2\langle \mathbf{V}_a(t) \cdot \mathbf{V}_b(t) \rangle. \quad (3)$$

After a sufficiently long time the absolute velocities of the two particles decorrelate and the mean-square relative velocity becomes just four times the eddy kinetic energy.

4. Data treatment

Due to the SOFAR system of acoustic transmission used in the TOPOGULF experiment, two different floats were never located simultaneously. However, all floats were positioned within a 6 hour interval. Furthermore, in this study we consider only daily positions, because the filtering done on the raw position estimates (see §2) may invalidate any result for times smaller than a few days. As in OCV, floats were partitioned between western and eastern basins, depending whether they were launched west or east of the MAR. No float pair constructed of a western float and an eastern float happened to satisfy the different criteria used to select the pair-separation-distance time series (see below) used in this statistical study. The original 14 western (respectively 12 eastern) float position time series were combined to yield $\binom{14}{2}$ (respectively $\binom{12}{2}$) pair-separation-distance time series 1000 days long. Pair separation distances of these 91 (respectively 54, because 12 pairs contain no data) time series were estimated with a 10^{-5} relative accuracy.

Since two floats move independently from each other if the separation distance is large enough compared to the more energetic scales, there is no need to consider large D_0 . In our float launching region, where R_{in} is ~ 25 km, structures with wavelengths of the order of 150 km will emerge because of the instability of the Azores current. Pair separation distance versus time plots (see figures 1, 2, 3 and 4 and the next section) show that once two floats have separated more than 150 km, they never come back within 30 km of each other (except for pairs 03-04 and 87-88 whose separations once shrank to 12 and 20 km respectively). In consequence, statistics will be presented only for D_0 values less than 120 km.

At the initial time (9 July 1983 in the west, 29 October 1984 or 11 September 1985 in the east respectively), there were 32 (respectively 12) pairs with $D_0 < 30$ km, but only 4 (respectively 5) pairs with $D_0 < 5$ km. To increase the number of pairs with small D_0 , 'chance' pairs could be considered as well. A 'chance' pair is created at the time (if any) the separation shrinks to a minimum of less than 50 km, either after launch or after the float separation has exceeded 150 km (so that the two floats

Western floats (91 pairs)

TABLE 1. Number of pairs versus separation classes. The first line contains pair numbers at the initial time: 9 July 1983 in the west; 29 October 1984 or 11 September 1985 in the east. The second line contains the 'chance' pair numbers, a 'chance' pair being defined if the separation shrinks to a minimum less than 50 km, either after launch or after the separation overshoots 150 km. The third line contains the pair numbers, for the minimum separation criterion and with a 120 days duration. The fourth line contains the 'random' pair numbers, a new 'random' pair being defined every 10 days from a given separation time series. For the western cluster, we have excluded roughly 50 % of the data because all the floats were swirling after launch within the cyclonic eddy shown on figure 1 (the numbers of pairs, had we kept the whole data set, are given within parentheses).

can be considered quasi-independent). Table 1 shows that only seven 'chance' pairs would result with $D_0 < 50$ km. This is clearly due to the fact that floats were launched initially in clusters (see OCV) and the minimum separations occurred either at launch or soon afterwards.

Consequently we tried another approach. We searched for the minimum separation between two floats during the entire life of a pair and recorded the evolution after that minimum, over 120 days (4 months). The same procedure was used in turn on the remaining time series (search for a second minimum and selection of the subsequent 120 days). Although it approximately doubles the number of pairs for small (< 20 km) D_0 (see table 1), a definite advantage for the statistics, this approach selects the separation time series corresponding to hyperbolic regions. The statistical results for the time evolution of mean-square separation between two particles with the same initial separation D_0 (to be presented in the next section) would thus be biased upwards.

To preserve as far as possible a 'random' sampling of the separation process, we have finally defined the separation-distance time series as 6 month portions of a given original time series, the different portions being initialized every 10 days. This procedure clearly weakens any assumption about the statistical independence of the different portions. However, results obtained from 30 day or 60 day re-initializations (presented in the next section) substantiate this approach. The 6 month duration was selected so that the large-time random walk can be clearly reached.

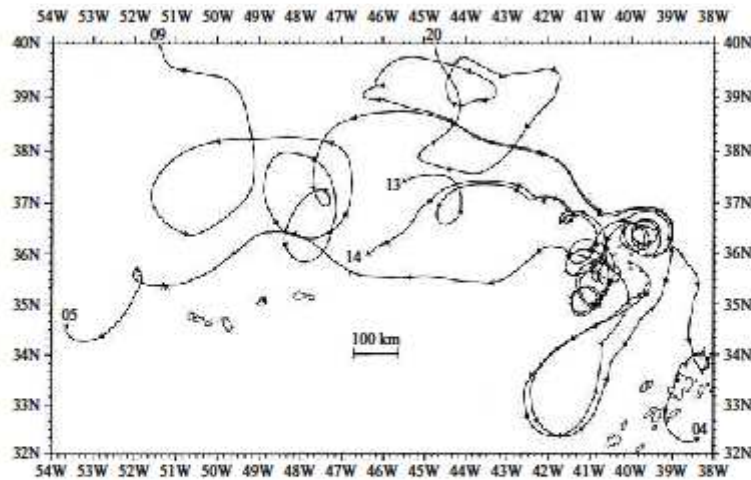

FIGURE 1. Float trajectories of three western pairs (TOPOGULF SOFAR floats 04 and 05, 13 and 14, 09 and 20) over 200 days after 9 July 1983. One arrowhead every 10 days. Floats are seen to separate swiftly once separation exceeds a few tens of km. These floats were launched between 4 July and 7 July 1983 at positions given by squares, but their trajectories are considered only after 9 July 1983 in this study.

Basically, all the statistical estimates will be given as a function of time, because $\langle \cdot \rangle$ is a Lagrangian average. Some statistical estimates will also be given as a function of D (the r.m.s. separation) since we know D^2 as a function of t and D_0 . But we must warn the reader that this is different from an ensemble average carried out among pairs of the same separation D , irrespective of time and initial separation D_0 . This will be illustrated in the following section.

5. Results

Although individual trajectories have been presented in OCV, it may help to visualize a few pair evolutions before going into the statistics proper. Figure 1 presents three western pairs over a 200 day period. Pair 09–20 (minimum separation 1.9 km) separated swiftly after 45 days, while pair 13–14 (initial separation 22 km) swirled within a cold-core cyclonic eddy for 180 days before separating swiftly thereafter (the minimum distance of 7.5 km occurred only a few days before the swift separation, see also figure 2). Pair 04–05 (minimum separation 2.1 km occurred more normally a few days after launching) separated more or less similarly. Pressure differences for paired floats were less than 30 dbar, for short separations, thus minimizing any vertical shear effect on pair dispersion (figure 2). Figure 3 presents one eastern trio. As described in OCV, there is clearly a topographic influence on the flow and the float dispersion. Figure 4 gives the temperature, pressure and separation evolutions for pair 87–88, with features similar to those of the western pairs. Since a trio gives three pairs in our analysis, it must be remarked that the three pair separations are not

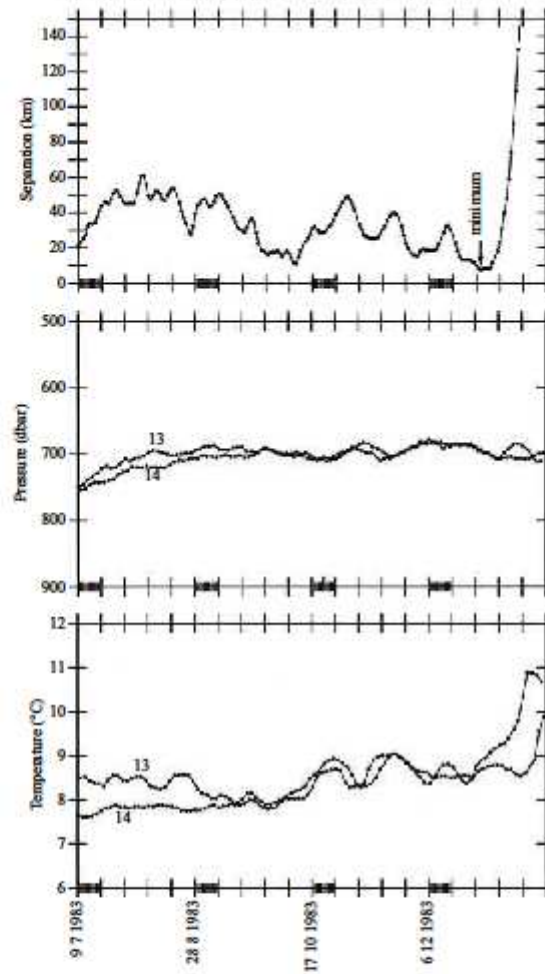

FIGURE 2. Temperature, pressure and separation time series (over 200 days after 9 July 1983) for the TOPOGULF SOFAR float pair 13-14. This pair was embedded in a cyclonic cold-core ring (where most of the 14 western floats were launched), and its separation distance oscillates between 10 and 60 km over 6 months after launch, as floats swirl within the ring. Absolute minimum ($D_0 = 7.5$ km) occurs only a few days before final fast separation.

totally independent, thus giving a number of degrees of freedom for our statistical estimates smaller than the number of pairs entering the statistics. A 'chance' pair can be identified on figure 4 for the pair 87-88.

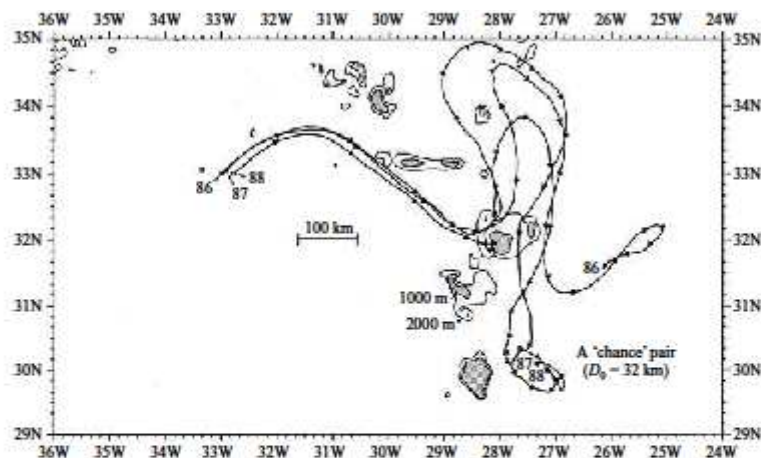

FIGURE 3. Float trajectories of a trio (TOPOGULF SOFAR floats 86, 87 and 88) over 200 days after 11 September 1985. One arrowhead every 10 days. This float trio remained closely packed while being advected by an eastward meandering jet but dispersed as the flow impinged on the seamounts found near 28–30°W.

We first investigated a possible anisotropy of the relative dispersion process. As shown in OCV, anisotropies appear in the single-particle diffusivities for time scales greater than a few months. Estimating the ratio of the r.m.s. zonal over r.m.s. meridional relative displacements for each class of pair separation shows a ratio close to one for scales less than a few hundreds km (figure 5). At greater distance, there is a tendency for zonal relative dispersion dominance, which becomes the rule near 1000 km, in agreement with the single-particle analysis.

Restricting our interest to scales less than a few hundreds km, the mesoscale band, the results presented next are averages over all directions. Shown in figures 6(a) and 6(b) is the dispersion $D^2(t, D_0)$ as a function of time and conditional upon initial distance D_0 ($D_0 < 50$ km), for the western and eastern floats respectively. The classes of distance (see table 1) were chosen as a compromise between having a sufficient number of realizations within each (order of 10 or more) and being sufficiently narrow not to bias the results.

As mentioned in the previous section, the statistics obtained by initializing 'independent' portions of the pair-separation-distance time series every 10 days do not depart significantly from those obtained by initializing every 30 days or every 60 days (but they are noisier), or even from those obtained from the independent portions selected with the criterion of minimum separation (although there is a more rapid growth). A few of these results will be shown for illustration, but we mainly show the results of the 10 day re-initializations. We must also point out here that since the western floats were all launched within a cyclonic cold-core eddy, where several remained trapped for a long time (see figure 1), the results obtained with those floats should be biased towards low values. By discarding most of the floats swirling in the initial eddy, the data set for the western floats is reduced by roughly 50% compared

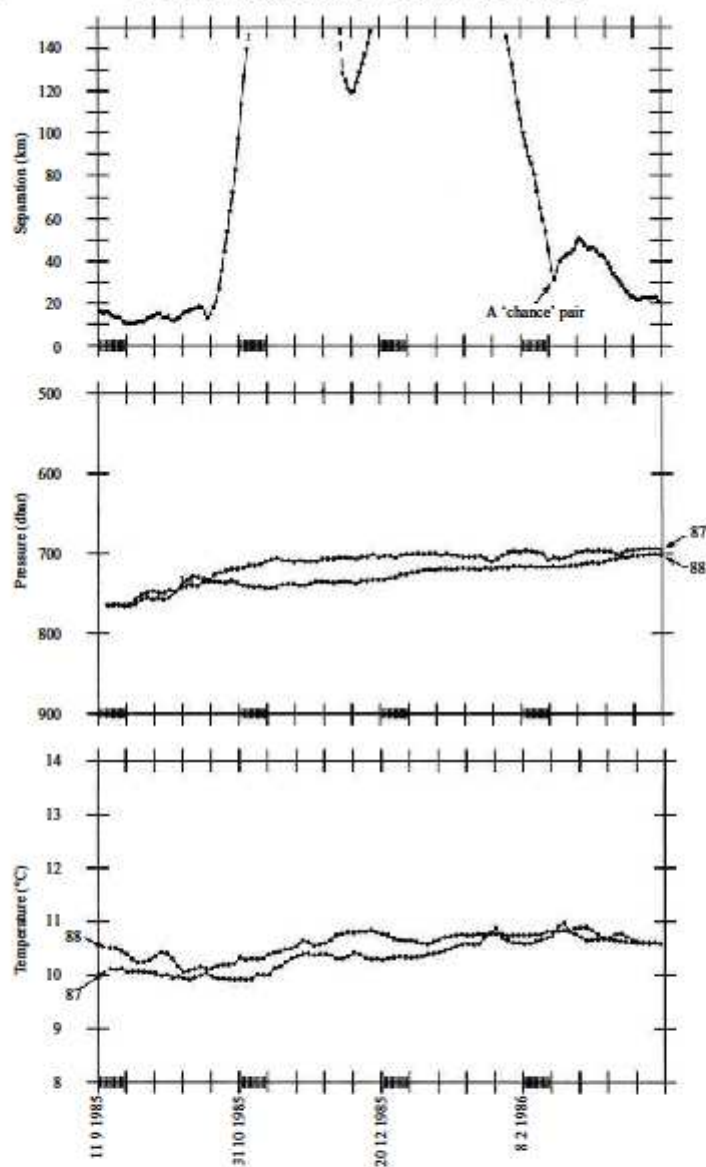

FIGURE 4. Temperature, pressure and separation time series for the TOPOGULF SOFAR float pair 87-88. A 'chance' pair is identified near 30°N 28°W on February 20, 1986 ($D_0 = 32$ km).

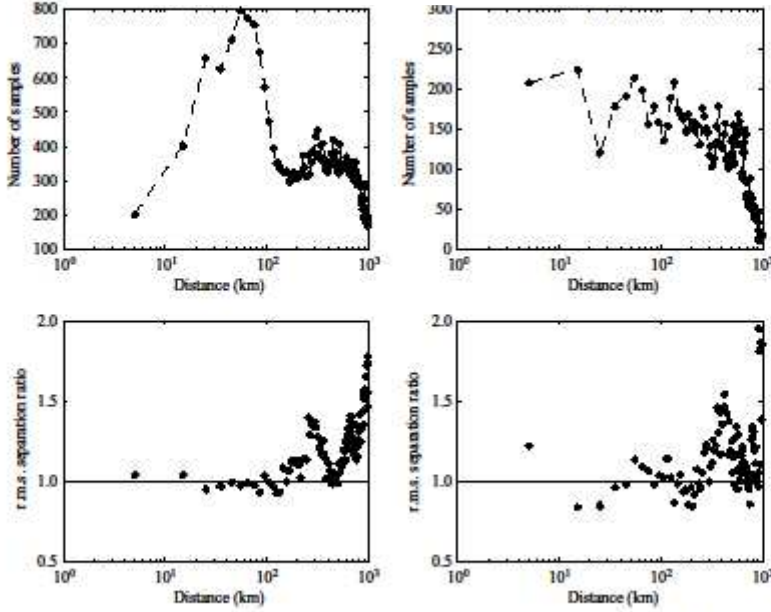

FIGURE 5. Ratio of the r.m.s. zonal and meridional separations within 10 km wide distance classes.

to the original set (see table 1). It is this reduced set that is used throughout this study, although some results are also given for the complete western data set.

When relative dispersion is plotted with semi-log axes (figure 6a), an exponential growth ($\sim e^{2t/\tau}$) is observed in the east for the smallest D_0 class with a time τ of ~ 12 days, from roughly a few days to three weeks. Whether a similar regime also occurs in the west for the smallest D_0 class is not clear (the corresponding error range is obviously underestimated because of correlated samples).

On the linear plots giving $(D^2(t, D_0))^{1/3}$ as a function of time (figure 6b), it is possible to identify a quasi-linear growth up to 60 days in the west and 120 days (or perhaps more) in the east. Using equation (1) we obtain an estimate of $a = c\epsilon^{1/3}$ as $(3/2) \times$ slope, whence the approximate values $a_W \approx 1.4 \times 10^{-3} \text{ m}^{2/3} \text{ s}^{-1}$ ($1.2 \times 10^{-3} \text{ m}^{2/3} \text{ s}^{-1}$ with the original data set) for the west and $a_E \approx 0.8 \times 10^{-3} \text{ m}^{2/3} \text{ s}^{-1}$ for the east, corresponding to slopes of $D^{2/3}$ versus time of $\sim 0.80 \text{ km}^{2/3} \text{ day}^{-1}$ ($\sim 0.70 \text{ km}^{2/3} \text{ day}^{-1}$ with the original data set) and $\sim 0.46 \text{ km}^{2/3} \text{ day}^{-1}$ respectively. This supports a Richardson regime as given by (1).

To test how well such a law fits the experimental data and find out if there is an asymptotic (at^3) regime, dispersion versus time is represented on a log-log plot. Figure 7 gives the dispersion behaviour for six initial separation classes chosen among the twelve D_0 classes (spanning a distance range from 0 to 120 km, see table 1). Except for the first D_0 class, the Richardson law (1) fits the data qualitatively well,

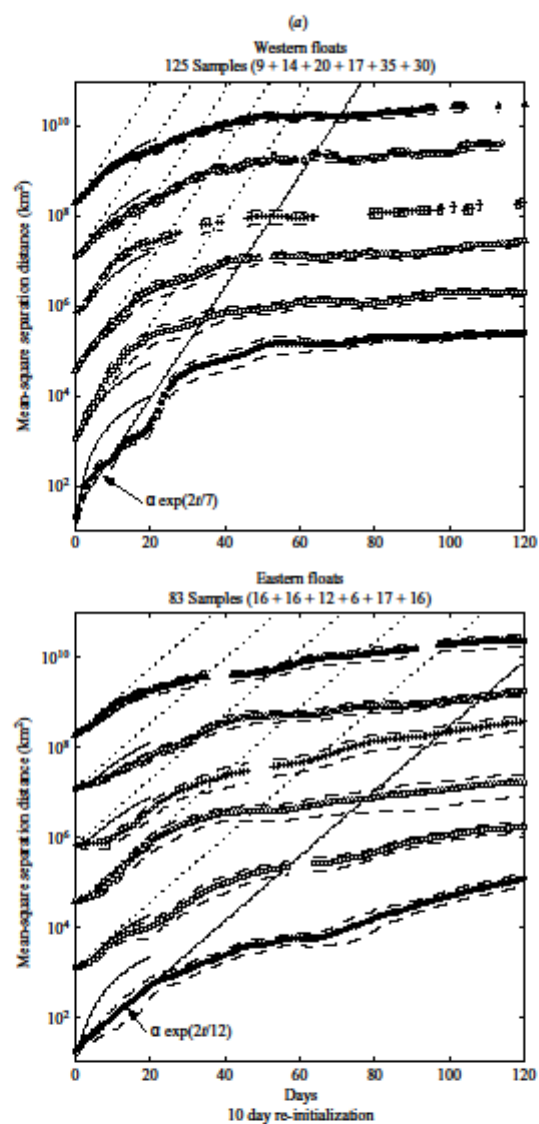

FIGURE 6(a). For caption see facing page.

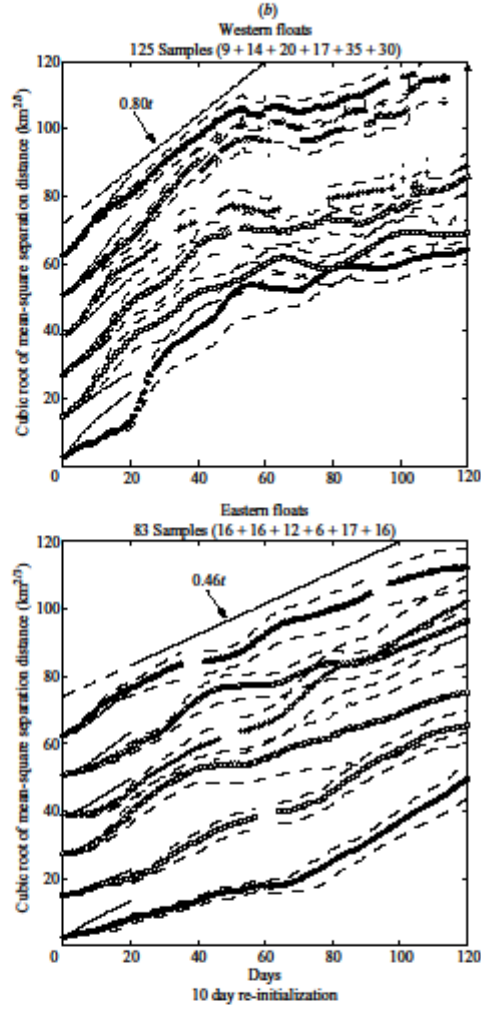

FIGURE 6. (a) Mean-square separation distance $D^2(t, D_0) \equiv \langle D^2(t, D_0) \rangle$ as a function of time and initial separation for the western (reduced) and eastern data sets. D_0 is within one of the six classes of distance $[0, 7.5[$, $[7.5, 15[$, $[15, 22.5[$, $[22.5, 30[$, $[30, 40[$ and $[40, 50[$ km. Corresponding curves are given by solid dots, open squares, open triangles, crosses, open dots and solid triangles respectively. For readability D^2 values corresponding to different D_0 are shifted by a power of ten. Broken lines indicate \pm one standard deviation on the mean. The fit $D_0^2 + \langle |\delta V_0|^2 \rangle t^2$ valid for small t is plotted for $0 \leq t < 20$ days. Only for the smallest class of initial distance and in the east does an exponential law stand out clearly. (b) $D^{2/3}(t, D_0)$ as a function of time and initial separation (same data and classes of distance as (a)). For readability D^2 values corresponding to different D_0 are shifted by a multiple of ten.

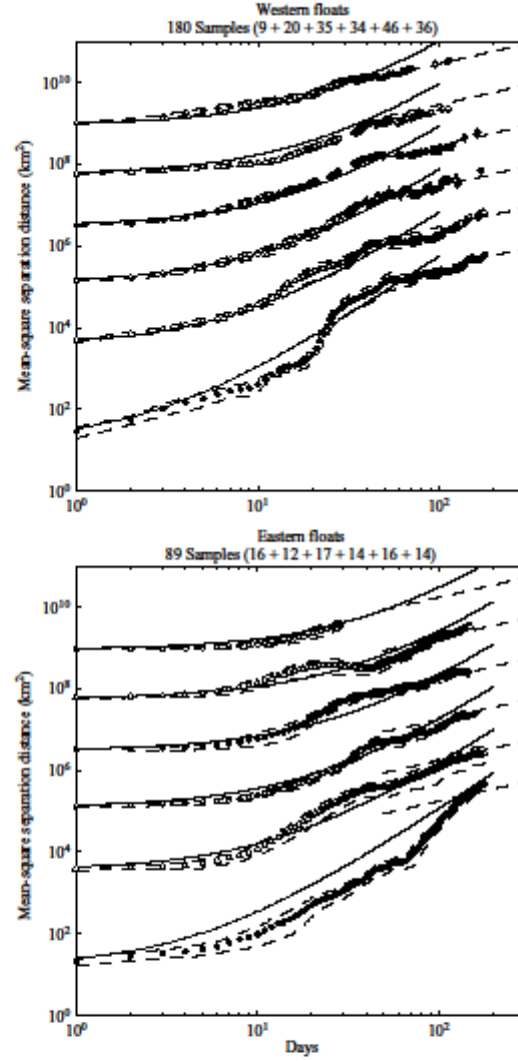

FIGURE 7. Mean-square separation distance $D^2(t, D_0)$ versus time and D_0 , for the western (reduced) and eastern data sets. Six D_0 classes are shown (from bottom to top, $D_0 \in [0, 7.5[$, $[15, 22.5[$, $[30, 40[$, $[50, 60[$, $[70, 80[$ and $[90, 100[$ km). Richardson law ($D^2 = (D_0^{2/3} + 2at/3)^3$ with $a_W = 1.4 \times 10^{-3} \text{ m}^2/3 \text{ s}^{-1}$ and $a_E = 0.8 \times 10^{-3} \text{ m}^2/3 \text{ s}^{-1}$) and large time Taylor law ($D^2 = 4K(\infty)t$ with $K_W(\infty) = 8.5 \times 10^3 \text{ m}^2 \text{ s}^{-1}$ and $K_E(\infty) = 5 \times 10^3 \text{ m}^2 \text{ s}^{-1}$) are also plotted. For readability D^2 values corresponding to different D_0 are shifted by a power of ten. Broken lines indicate \pm one standard deviation on the mean.

before the random walk regime ($4 Kt$) occurs ultimately. In agreement with equation (1), an asymptotic t^3 regime is only obtained after $D^2(t, D_0)$ becomes much greater than D_0^2 .

Two-particle diffusivity $Y(t, D_0)$ is calculated by finite time differencing $D^2(t, D_0)$ and is plotted as a function of $D(t, D_0)$ on figure 8. Averaging individual values within distance intervals reveals, as expected, a reasonable fit to the law $Y(t) = d\chi^{1/3} D^2$ (with $(d\chi^{1/3})^{-1} = \tau = 12$ days in the east) and to the law $Y(t) = aD^{4/3}$ (with $a_W = 1.4 \times 10^{-3} \text{ m}^{2/3} \text{ s}^{-1}$ and $a_E = 0.8 \times 10^{-3} \text{ m}^{2/3} \text{ s}^{-1}$). Although roughly confirmed in the east, the exponential (or D^2) regime is not resolved in the west, perhaps due to the paucity of data for small distances or because it simply does not exist. In the east, the transition to the Richardson (or $D^{4/3}$ regime) appears at separations between roughly 20 and 30 km. With 30 day or even 60 day re-initializations, the two regimes (in the east) and the corresponding statistical laws, are similarly resolved (open squares or open triangles in figure 8). This gives support for our 10 day re-initialization procedure.

Using the original time series without re-initializations, we have also computed the doubling times $T(D_n)$, defined as the mean time for a particle pair separation to grow from D_n to $2D_n$ (with $D_1 = 3$ km and absorbing barriers). In the east, $T \sim 9$ days (or $\tau = T/\ln 2 \sim 13$ days) for the first four estimates, then varies roughly as $D^{2/3}$ for the next three estimates. In the west, T varies very roughly as $D^{2/3}$ for the seven estimates, supporting the Richardson regime but not an exponential growth.

We had thought of obtaining an independent check of the statistical laws relating Y to the distance by calculating a relative diffusivity $Y_E(D)$ as the mean of $D(t) \cdot \delta V(t, D_0)$ from all pairs with the same D (in practice of course within a small interval $[D, D + dD]$), irrespective of time and initial separation D_0 . By so doing we would obtain a large number of samples (without re-initializations). Being calculated with what amounts to an Eulerian operation, $Y_E(D)$ is clearly different from our previous average, conditional on initial positions. In fact, when this unconditional averaging is carried out with our data, $Y_E(D)$ is roughly half $Y(D)$. The following argument gives the origin of the difference. Considering the realizations $D(t, D_0)$ with D_0 fixed (in practice within a small interval $[D_0, D_0 + dD_0]$), one observes that $Y_E(D, D_0)$ is generally smaller than $Y(D, D_0)$ for D less than 100–200 km. This is caused by some of the separation-distance time series that remained fluctuating in this distance range, whence a negligibly small contribution to Y_E because $\sum dD^2/dt = D_{k+1}^2 - D_k^2$ (if D^2 increases) is cancelled by $\sum dD^2/dt = D_k^2 - D_{k+1}^2$ (as D^2 decreases). Meanwhile, the other separation-distance time series grow much more rapidly, whence $(D^2(t, D_0))^{1/2}$, i.e. the r.m.s. average (at a given time) of both ‘slow’ and ‘fast’ separation distances, which swiftly leaves the range of D less than 100–200 km. This explains why $Y_E(D)$, which is obtained after averaging of all the D_0 contributions, is smaller than $Y(D)$ for D less than 100–200 km, but (loosely) tends to $Y(D)$ for greater distance. It is worth noting, however, that the shape of Y_E versus D is not very different from that obtained from the proper conditional averages. Whether Y_E is of physical significance and if so, how it relates to Y , remains to be studied.

Let us now suppose that for $D_0 > 30$ km, the Richardson law (1) applies from $t = 0$ (possibly discarding the first few days, if necessary) until the time the Taylor or random walk regime is reached. One can say that the asymptotic t^3 regime is reached only for a short time period (e.g. a few days before the Taylor regime). But let us make a shift of the time, given by $\tilde{t} = t + t_0 = t + 3D_0^{2/3}/2a$. Then (1) can be rewritten as $D^2(t) = 8a^3\tilde{t}^3/27$ and now one can say that the regime is perfectly asymptotic (in \tilde{t}). So shifting in time the different dispersion curves (such as given in figure 7)

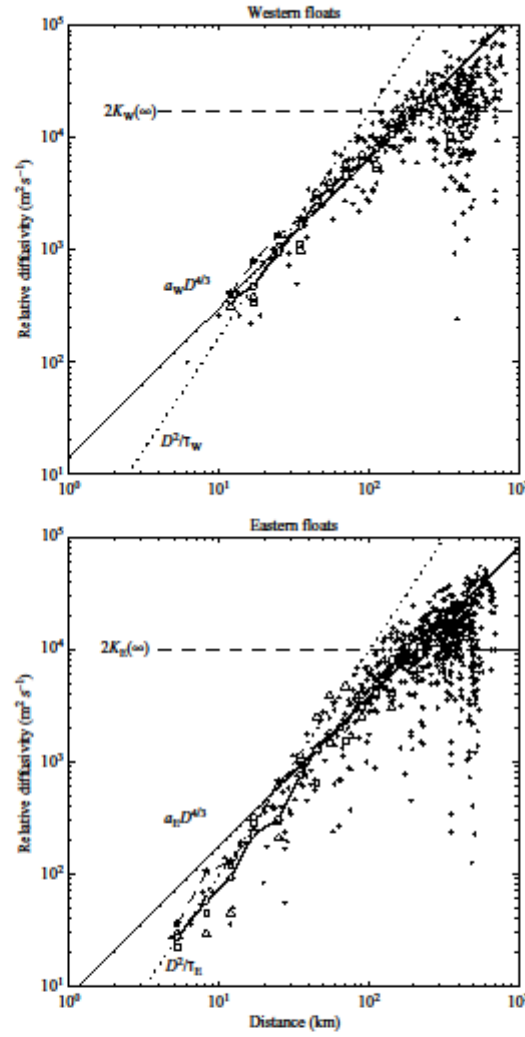

FIGURE 8. Relative diffusivity $Y(t, D_0) = \frac{1}{2} (d/dt) D^2(t, D_0)$ versus D . Crosses give individual estimates obtained by finite differentiating the twelve mean-square separation distance time series corresponding to the twelve D_0 classes given in table 1 and for 10 day re-initialized time series. Open dots are weighted averages over values found within distance intervals. Open squares and triangles give the weighted averages for 30 day and 60 day re-initialized time series respectively. Stars give the corresponding evolution from the portions selected with the minimum separation criterion. The $a_w D^{4/3}$ and D^2/τ laws are given with $a_w = 1.4 \times 10^{-3} \text{ m}^{2/3} \text{ s}^{-1}$ and $a_E = 0.8 \times 10^{-3} \text{ m}^{2/3} \text{ s}^{-1}$, and with $\tau_w = 7$ days and $\tau_E = 12$ days respectively.

corresponding to the eight D_0 classes with $30 \leq D_0 < 120$ km, and averaging, we obtain a unique curve (independent of D_0), given in figure 9. The different temporal shifts, calculated from a_w and a_E are given in the caption of figure 9. Since these composite plots are constructed under the assumption of a cubic regime, they do not prove its existence, but show that the data agree with such a regime. They combine the results obtained so far: if we assume a transition scale near 25 km (thus corresponding to a wavelength of about 150 km), there is a possible exponential dispersion at smaller scales, a clear-cut Richardson regime over the 40–300 km distance range and a random walk regime reached for greater D , faster in the west (after 2 months) than in the east (after 4 months). The possibility that the western dispersion for the smallest D_0 class may follow a Richardson regime is not ruled out (solid dots or stars on figure 9), whereas the corresponding eastern dispersion departs clearly from the t^3 curve, over the first ten days (either with 10 day or 60 day re-initializations, or even with portions selected with the minimum criterion).

The mean-square relative velocities $\langle \|\delta \mathbf{V}(t, D_0)\|^2 \rangle$ are given on figure 10 for the twelve D_0 classes. It is pleasing to note that they show the same kind of time evolution as those from Babiano *et al.* (1990, their figure 2a). Although it has been argued that within the inverse energy cascade range, $\langle \|\delta \mathbf{V}(t, D_0)\|^2 \rangle$ should vary as t (Monin & Yaglom 1975; Babiano *et al.* 1990), this is not visible here, nor in Babiano *et al.*'s (1990) or Kowalsky & Peskin's (1981) numerical results, probably because the assumptions underlying the theoretical result are too stringent. Nevertheless, when t is large, the mean-square relative velocity equilibrates to four times the kinetic energy in agreement with (3), giving rough estimated values of 30 (60) days for the pair relative velocity decorrelation time scale in the west (east). Since as $t \rightarrow 0$ the mean-square relative velocity tends towards $Z D_0^2$, we can estimate the enstrophy Z , obtaining values between 0.6 and 0.06 day^{-2} in the west, and between 0.2 and 0.02 day^{-2} in the east. A better estimate for Z should come from the characteristic time of relative dispersion $\tau_r(t, D_0) = D^2(t, D_0)/Y(t, D_0)$ as a function of D . Babiano *et al.* (1990) have shown that it reaches a minimum equal to $2/Z^{1/2}$ over the distance range of the exponential regime. Figure 11 shows the results for τ_r , in approximate agreement with such an interpretation, providing $Z \approx 0.16 \text{ day}^{-2}$ in the west and 0.04 day^{-2} in the east (or a minimum characteristic time τ of 5 days in the west and 10 days in the east).

The separation probability density functions (p.d.f.) were estimated at 10 day intervals. Figure 12 gives the p.d.f.s (rescaled so that their variance is unity) for initial separations in the ranges $0 \leq D_0 < 7.5$ km and $30 \leq D_0 < 40$ km, for the east (western p.d.f.s, not shown, are similar but slightly noisier). The comparison with an assumed Gaussian distribution for D , i.e. a Rayleigh distribution for $\|D\|$ (D is a sample separation, not a r.m.s. value), is encouraging for large D_0 , but not at all for small D_0 , whose observed distribution contains many more small separations. This result agrees with Davis (1985), who instead used surface drifters off the California coast. Highly kurtosed distributions were also obtained experimentally (with 10^4 pairs) by Jullien *et al.* (1999), for small $D_0 (= D_I/50)$. Their distributions corresponding to different times for which the Richardson scaling holds, i.e. for $D(t, D_0)$ greater than (or of the order of) D_I , reveal that the separation process is self-similar in time in the range considered (this seems likely for our data too). A best fit for the tails of their p.d.f.s (also rescaled), is $\exp(-\alpha s^{1/2})$ with $\alpha \sim 2.6$, thus strongly non-Gaussian. As a comparison the distribution given by $2\exp\{-2s^{1/2}\}$ plotted on figure 12 (small D_0 case), is seen to fit roughly our data. Due to our reduced number of samples however, we cannot be more quantitative.

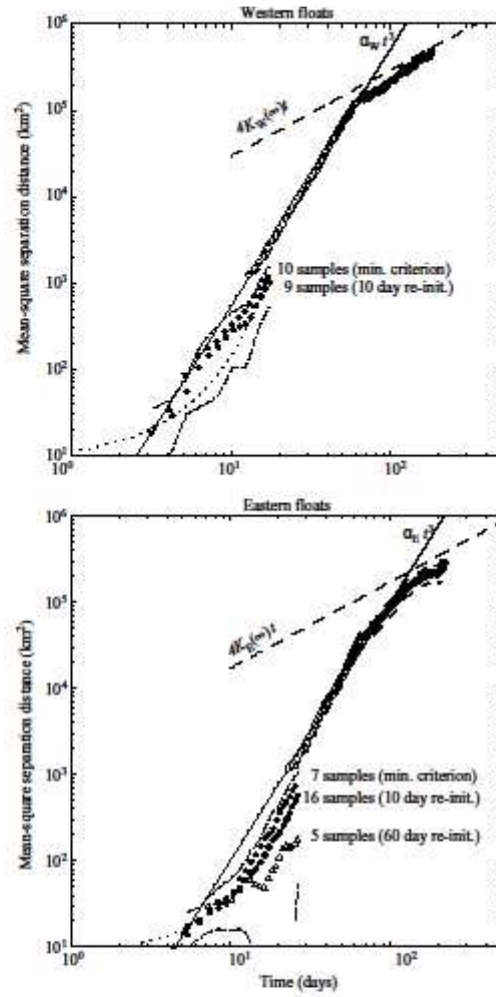

FIGURE 9. Mean-square separation distance versus time obtained by averaging at a given time, the individual mean-square separation distance curves corresponding to $D_0 > 30$ km, but shifted in time as explained in the text, so that they start as if they were already in the asymptotic Richardson regime. Actually the shifts are 13, 16, 18, 20, 22, 24, 26 and 29 days in the west and 23, 27, 31, 35, 39, 42, 45 and 50 in the east. Broken lines indicate \pm two standard deviations on the mean. Solid dots (open triangles) give the mean-square separation distance, for the smallest D_0 class for the 10 day (60 day) reinitialized time series, and shifted in time as if it had started in the asymptotic Richardson regime. Stars give the corresponding evolution for the portions selected with the minimum separation criterion. Clearly the eastern dispersion does not follow a t^3 law over the first 10 days.

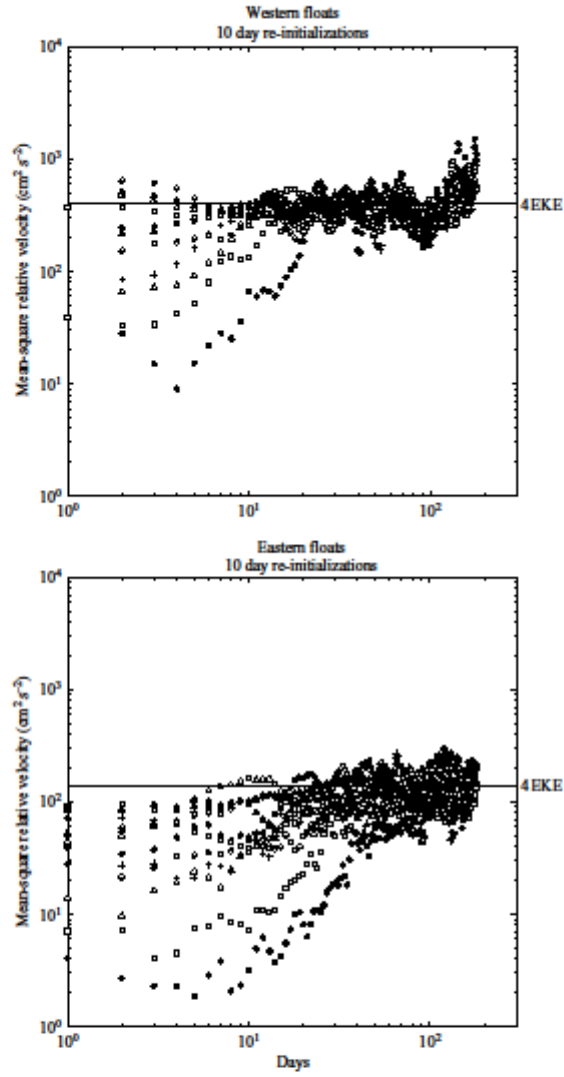

FIGURE 10. Mean-square relative velocity $\langle \|\delta V(t, D_0)\|^2 \rangle$ as a function of time. Symbols corresponding to the first six D_0 classes are as in figure 6. The same symbols are used similarly for the last six D_0 classes (table 1).

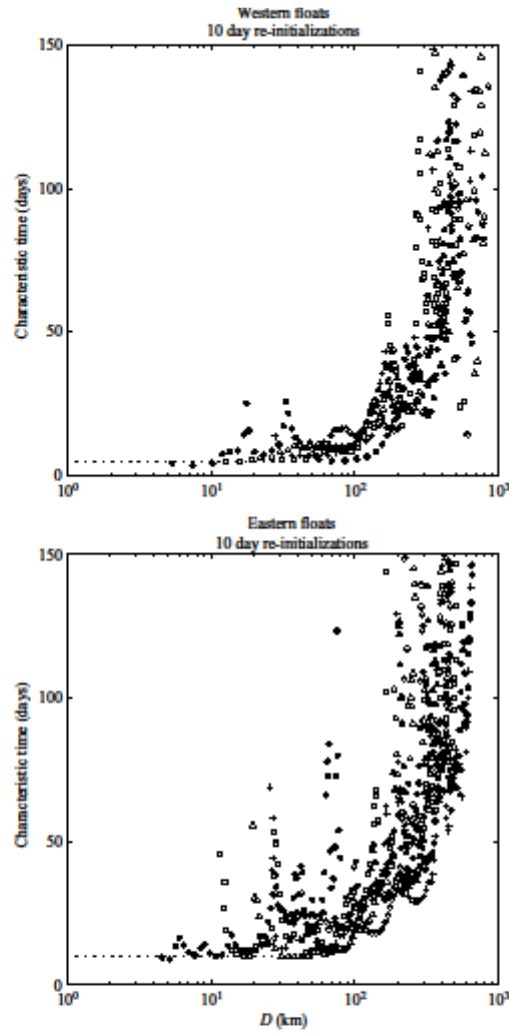

FIGURE 11. Characteristic time $\tau_y(t, D_0) = D^2(t, D_0)/Y(t, D_0)$ as a function of D and D_0 and for the first six D_0 classes ($0 \leq D_0 < 50$ km).

6. Discussion

At scales less than the Rossby radius of deformation (here for $D < 25$ km), our observation of a possible exponential regime gives support for the traditional enstrophy

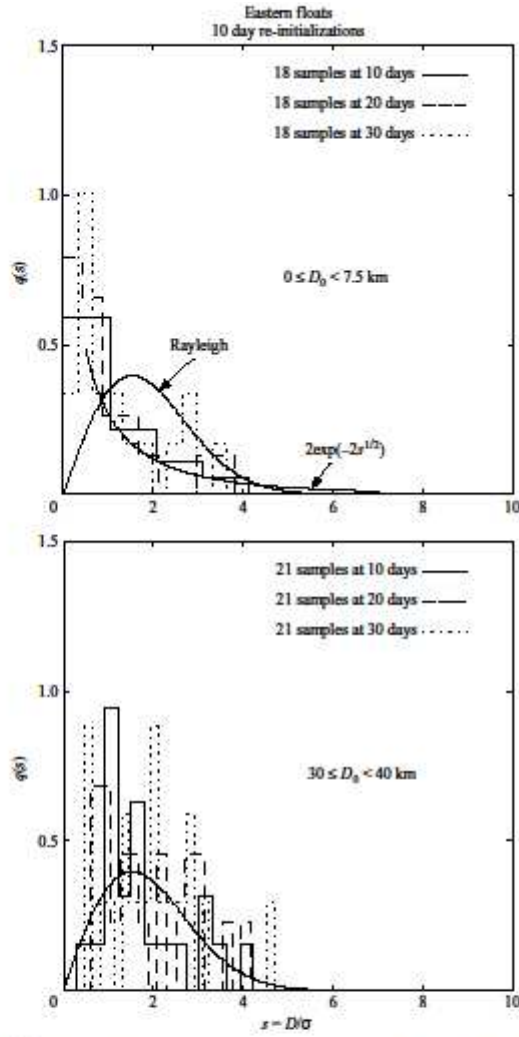

FIGURE 12. Probability density functions $q(s, t)$ of rescaled pair separations $s = D/\sigma$ (here $D = |D|$) after 10, 20 and 30 days, for small ($0 \leq D_0 < 7.5$ km) and large ($30 \leq D_0 < 40$ km) initial separations, and for the eastern floats. $p(D, t)$ is the original p.d.f., whence $q(s, t) = \sigma p(\sigma s, t)$ where σ^2 is the variance of D . The Rayleigh distribution (rescaled) is given by $\lambda s \exp(-\lambda s^2/2)$ with $\lambda = (4 - \pi)/2$.

cascade to small scales. However in geostrophic turbulence long-lived coherent vortices are found, along with more random fluctuations (McWilliams 1984). These coherent features are the signature of elliptic regions. Since numerical simulations of two-dimensional turbulence by Elhamaidi, Provenzale & Babiano (1993) indicate that hyperbolic regions occupy a larger domain than elliptic ones, they will be favoured by an initial seeding of particles over a regular grid. Thus, the exponential separation may simply result, for small enough time and separation, from the pre-eminence of these hyperbolic regions.

The recent analysis of Lacasce & Ohlmann (2003) of surface trajectories in the Gulf of Mexico clearly shows an exponential growth with $D_0 \leq 1$ km and for separations smaller than 40 km. Although such drifters may experience Ekman drift, windage and surface flow convergence, these authors argue that an enstrophy regime is possible for D less than R_m (45 km in the Gulf of Mexico). The compilation of subsurface float experiments by Lacasce & Bower (2000) did not indicate an exponential regime and their first explanation (supported by the above surface results) was that not enough pairs with small initial separation were observed. This may be why no exponential growth was revealed in our western cluster. A large number of pairs is needed to ensure the results are statistically significant: our nine pairs in the west were not enough. Only with a mean $D_0 \sim 4$ km and 16 pairs in the east were we able to obtain an exponential growth. Another recent analysis by Colas (2003) of subsurface float pair separations (with $D_0 \leq 10$ km) in the eastern North Atlantic also supports the idea of an exponential regime but only marginally. The difference between our two clusters may also be of topographic origin: there are examples of pairs which separate when hitting seamounts in the east, but none in the west. The exponential regime found for our eastern cluster in the ocean interior needs to be confirmed with better statistics, and far from topographic influences.

Closer to a realistic oceanic case than Babiano *et al.*'s (1990) results, numerical simulations of pair dispersion in an eddy-resolving wind-driven, stratified oceanic model carried out by Berloff *et al.* (2001) confirms the existence of an initial exponential regime with values of τ of order 10 days in regions with eddy kinetic energy of order $100 \text{ cm}^2 \text{ s}^{-2}$. This agrees with our experiment since τ is 12 days for eastern pairs. Lagrangian integral time scales T_L have approximately the same values (7–10 days in the east, 5–6 days in the west) whereas the western cluster has eddy kinetic energy (EKE) three times larger than the eastern cluster ($100 \text{ cm}^2 \text{ s}^{-2}$ versus $35 \text{ cm}^2 \text{ s}^{-2}$). If we apply the parameterization given in OCV (that seems to fit mid-latitude oceanic data), that is $K_{11} + K_{22} = K(\infty) \approx \gamma R_m \text{EKE}^{1/2}$ (with $\gamma \sim 3$ at 700–1000 m depth) and if we assume that $\tau \approx T_L$, we obtain a prediction of the exponential law for any region: since $K(\infty) = 2\text{EKE}T_L$ we have $2\tau \approx \gamma R_m \text{EKE}^{-1/2}$. For the EOLE and TWERL atmospheric experiments, Morel & Larcheveque (1974) and Er-El & Peskin (1981) respectively give $\text{EKE} \approx 150 \text{ m}^2 \text{ s}^{-2}$, $R_m \approx O(1000)$ km (at mid-latitudes). Their observed value of $\tau \approx 3$ days is of the order of the predicted value $\tau \sim 1.5$ days.

Since the Richardson regime must be found in two-dimensional turbulence for distances larger than those associated with the exponential regime, coarse resolution data are sufficient to detect it. Lacasce & Bower (2000) confirmed the $D^{4/3}$ law but only for experiments in the western basin of the North Atlantic. The impressive older data compilation by Okubo (1971) combines two- and three-dimensional aspects making comparisons difficult. For large-scale atmospheric data, the Richardson regime was not examined by Morel & Larcheveque (1974), while much scatter remains in Er-El & Peskin's (1981) t^3 fit to their data. This may be due to the factor of 10

which exists between the scales of atmospheric and oceanic motions making the homogeneous and stationary turbulence assumptions more difficult to justify for the larger-scale atmospheric motions. The results of two-dimensional numerical forced experiments comply more closely with expectations. The t^3 asymptotic regime was observed by Babiano *et al.* (1990) but only for D_0 much smaller than their injection scale. Furthermore the regime is reached later as D_0 increases (their figure 4). We point out that this behaviour may be explained simply by the form $(D_0^{2/3} + 2at/3)^3$ of the integrated Richardson law (1). When D_0 is larger than the injection scale (the Rossby radius of deformation in our experimental context), the temporal law (1) is recovered over the whole time range and we propose therefore that this form (1) has to be preferred over the asymptotic t^3 limit when tests of the Richardson regime are sought. No such ambiguity appeared in Jullien *et al.*'s (1999) laboratory experiment: since their D_0 values were much smaller than their injection scale D_I , the t^3 asymptotic was reached as soon as D was larger than D_I .

As relative dispersion in a mean shear may also produce a t^3 regime (e.g. Bennett 1987), Lacasce & Bower (2000) suggested that some of their $D^{4/3}$ results could be caused by such an effect due to the proximity of strong mean currents. Given the isotropic character of the dispersion process in the TOPOGULF data (figure 5), this explanation, however, seems unlikely in our case.

The $D^{4/3}$ scaling for the diffusivity that we observe may well be associated with the existence of an inertial regime over the relevant scales (40–300 km). We have estimated values for $a = c\varepsilon^{1/3}$ to be about $0.8 \times 10^{-3} \text{ m}^{2/3} \text{ s}^{-1}$ and $1.4 \times 10^{-3} \text{ m}^{2/3} \text{ s}^{-1}$ respectively for the eastern and western cluster. Available estimates (Monin & Yaglom 1975) vary between 10^{-4} and $10^{-2} \text{ m}^{2/3} \text{ s}^{-1}$, thus consistent with our estimates.

The quantity ε in two-dimensional turbulence represents the rate at which kinetic energy is transferred up scale. Alves & Colin de Verdière's (1999) numerical integrations of the nonlinear eddy generation process for the region analysed herein (the area of the Azores subtropical front) indicate that eddies appear initially through the baroclinic instability of the quasi-geostrophically balanced jet at wavelengths (scales) larger than 50 (8) km with a broad maximum at 150 (25) km (scale is more appropriate to compare with separation distance). After about 100 days, there is evidence of an upscale (inverse) energy cascade, the energy-containing wavelengths (scales) reaching 240 (40) km. From this, we could conclude that the injection of eddy energy occurs towards the small-scale end of our postulated inertial range and that we witness evidence of an inverse energy cascade. The eddy equilibration does not reach the full barotropic state, however, a process which has been shown recently by Smith & Vallis (2001, 2002) to be caused by the surface-intensified structure of the oceanic stratification which allows a significant part of baroclinic energy to remain near the scale R_{int} . With their interpretation in mind, the inertial eddy–eddy interactions that we infer in the main thermocline at scales larger than R_{int} would be the result of an upscale energy cascade for the barotropic mode and a downscale cascade for the baroclinic modes. In order to compare with other experiments, we choose ε to be the eddy kinetic energy conversion from the mean potential energy. Alves & Colin de Verdière (1999) estimated this energy flux $(-g\overline{w'\rho'}/\rho_0)$ to be $10^{-10} \text{ m}^2 \text{ s}^{-3}$ and when such a value is used as a proxy for ε , the constant c of proportionality between Y and $\varepsilon^{1/3} D^{4/3}$ is about 2 or 3. Dedicated experiments on geostrophic turbulence and theory will be needed to test the value of this definition.

Finally, according to our data, the Gaussian distribution, proposed by Batchelor (1952), seems to be ruled out when D_0 is small (compared to the energy injection scale D_I) and for times when the Richardson regime begins to hold, that is when D is order

of or slightly greater than D_I (30 days after launch in our experimental results), in agreement with the two-dimensional turbulence experimental results of Jullien *et al.* (1999) or the numerical simulations by Boffetta & Sokolov (2002). However, the latter authors show that the distribution evolves to a Gaussian as time increases, but our data did not allow us to explore this. Whether the observed (and rescaled) oceanic distribution is identical to the one found in Jullien *et al.*'s experiment for $D_0 \ll D_I$, and whether the Gaussian distribution is adequate for separations conditional upon an initial $D_0 \gg D_I$, or at large time, must await confirmation until a larger observational data base is gathered.

We wish to thank Armando Babiano, Xavier Carton, Bach-Lien Hua and Jim McWilliams for discussions regarding this work, and all reviewers for helping us to clarify the paper.
