SUMMARY

The discrete element method (DEM) presents an alternative way to model complex mechanical problems of silica glass, such as brittle fracture. Since discontinuities are naturally considered by DEM, no complex transition procedure from continuum phase to discontinuum one is required. However, to ensure that DEM can properly reproduce the silica glass cracking mechanisms, it is necessary to correctly model the different features characterizing its mechanical behavior before fracture. Particularly, it is necessary to correctly model the densification process of this material which is known to strongly influence the fracture mechanisms. The present paper proposes a new and very promising way to model such process which is assumed to occur only under hydrostatic pressure. An accurate predictive-corrective densification model is developed. This model shows a great flexibility to reproduce extremely complex densification features. Furthermore, it involves only one calibration parameter, which makes it very easy to apply. This new model represents a major step towards accurate modeling of materials permanent deformation with the discrete element method, which has long been a huge challenge in applying this method for continuum problems.

1. INTRODUCTION

Silica glass, which is typical of amorphous solids, belongs to the category of anomalous glasses [13, 14] and is known to exhibit a complex mechanical behavior. Under hydrostatic pressures up to approximately 8 GPa , this material behaves in a perfectly elastic manner. Beyond 8 GPa , it begins to exhibit signs of permanent deformation known as densification [12, 38, 40, 59, 60, 71]. Densification of silica glass which is defined as permanent volume change (or permanent density change) is quite different from plasticity of crystalline solids. Indeed, this last phenomenon is volume-conservative and can only occur under shear stress. Once initiated, the densification process continues to evolve with pressure until approximately 20 GPa , at which the permanent volume

change can reach 17.4% [36, 38, 40, 59]. During this process, the mechanical properties of silica glass increase with increasing pressure [12, 13, 14, 38, 59, 63]. According to references [36, 38], Young's modulus and Poisson's ratio of silica glass present a spectacular augmentation of respectively 46% and 56% at the end of densification. Beyond 20 *GPa*, the densification process stops evolving and the material regains its elastic behavior. Although the role of hydrostatic pressure on the densification of silica glass is now well known, the role of shear stress on this phenomenon has been a contentious issue since the first work on the subject [12]. Several experimental works investigating this issue can be found in the literature, some of which are controversial. Some works [17, 18, 21] state that shear stress has no influence on the final densification level (it may only have kinetic effects, *i.e.* effects on the rate at which silica glass densifies under hydrostatic pressure), whereas others [16, 45, 59, 67] hold the opposite view. To corroborate these works, several numerical studies have also been conducted [32, 39, 40]. In a recent previous paper [32], a silica glass model has been developed using an assumption of no shear effects on densification. Application of this model to simulate various silica glass problems at both microscopic and macroscopic scales has led to acceptable numerical results, which favors the relevance of the adopted assumption. Further research effort is required to get over this issue. Another challenging feature of silica glass is concerned with its fracture behavior. The great complexity of this behavior lies in the fact that it depends on several parameters such as microscopic defects and flaws existing in the material, but also on the environmental conditions which can strongly modify the fracture properties [49, 68, 69].

Due to its anomalous and complex mechanical behavior, accurate description and modeling of silica glass has long been a challenge for continuum methods, such as the finite element method (FEM) [73, 74], and the smoothed particle hydrodynamics (SPH) [42, 43, 56]. Indeed, certain inherent drawbacks caused by the reliance of these methods on continuum mechanics, generally requiring computation mesh, and unsuitability in dealing with discontinuities are still not adequately addressed. In contrast, discrete (or discontinuum) methods [6, 19, 20, 33, 34, 41, 54, 55], which are based on discrete (Newtonian) mechanics and do not rely on any kind of mesh, can naturally provide solutions for major of these drawbacks. Using these methods, the domain of interest is modeled by a set of discrete elements (particles) that can interact with each other. According to the analysis scale, the discrete methods most commonly used can be classified into three classes: quantum mechanical (or *ab initio*) methods (QMs), atomistic methods (AMs) and discrete element methods (DEMs) [33, 44]. QMs are used for material simulation at the atomic scale ($\sim 10^{-9} m$), in which the electrons are the players. The molecules are treated as collections of nuclei and electrons whose interaction is directly dictated by their quantum mechanical state, without any reference to chemical bonds. Examples of QMs are quantum Monte Carlo [24], density-functional theory [26]. These methods are generally very accurate since they hold out the possibility of performing simulations without prior need for tuning. However, they are extremely expensive and can only be applied on very small domains of a few nanometers size. AMs are used for material simulation at the microscopic scale ($\sim 10^{-6} m$), where atoms are the players. These methods ignore the electronic motions and compute the energy of a system as a function of the atomic positions only. The interaction laws between particles (atoms) can be described by empirical interatomic potentials that encapsulate the effects of bonding between them. Examples of AMs are molecular mechanics (statics) (MM) [29], molecular dynamics (MD) [3, 4, 51]. Although they are less accurate than QMs, the atomistic methods can be applied to much larger systems

involving up to 10^9 atoms [1]. However, their application to simulate realistic engineering problems remains at present elusive due to overwhelming computation costs. DEMs are used for material simulation at the mesoscopic scale ($\sim 10^{-4} m$), where lattice defects such as dislocations, crack propagation, and other microstructural elements are the players. These methods can broadly be regarded as a generalization of the atomistic methods, where more complex interaction laws (derived by calibration or from phenomenological theories) are used. The atomic degrees of freedom are not explicitly treated and only larger-scale particles are considered. Although DEMs were originally developed for granular materials (*e.g.* grains [35] and powders [47]), they have become an alternative way to model complex continuum problems, for which traditional continuum methods may not provide the most appropriate computational framework. Different variations of discrete element methods can be found in the literature. The reader is invited to read the interesting review papers recently published by Lisjak and Grasselli [41] and Potyondy [55] for more details. These variations are distinguished according to several criteria, including the type of contact between bodies, the representation of deformability of solid bodies, the methodology for detection and revision of contacts, and the solution procedure for the equations of motion [37]. Examples of DEMs are the distinct element method developed by Cundall and Strack [19, 20], which is considered as the factory method of DEMs, and the bonded-particle method (BPM) developed by Potyondy *et al.* [53, 54, 55] to model rocks. With the latter approach, a material is modeled as a statistically generated assembly of non-uniform-sized rigid circular or spherical particles that may be bonded together at their contact points. Mainly, two types of bonds are used in BPM: contact bond and parallel bond [54]. In the contact bond model, an elastic spring with constant normal and shear stiffnesses acts at the contact points between particles, allowing only forces to be transmitted. In the parallel bond model, both forces and moments are transmitted between particles using a set of elastic springs uniformly distributed over a finite-sized section lying on the contact plane and centered at the contact point. In the context of DEMs, a particular approach can also be cited: the combined (hybrid) finite-discrete element method (FDEM) [46, 50, 57, 70]. With this variation, the simulation starts with a continuous representation of the domain of interest, then, upon satisfying some failure criterion, formation of new discrete bodies is allowed. This approach blends continuum techniques (for the computation of internal forces and for the evaluation of a failure criterion, *etc.*) with discrete concepts (for detecting new contacts and for dealing with the interaction between the newly formed discrete bodies, *etc.*). Recently, another variation of DEMs has been developed by André *et al.* [6, 7, 33] to model continuum problems, for which the continuity assumption can become disabled during simulation. In this approach, the neighboring discrete elements (rigid spheres) are bonded by permanent cohesive beam bonds, of which mechanical properties are determined by calibration. The Euler–Bernoulli beam theory [65] is used to compute the beam forces and moments.

As mentioned by André *et al.* [6, 7, 33], their approach is well adapted to model complex continuum problems. Particularly, it seems to be well suited to the simulation of silica glass problems that involve fracture [8, 32]. Since discontinuities are naturally taken into account by this DEM variation, there is no need for complex transition procedure from continuum phase to discontinuum one. However, to ensure that this method can properly reproduce the silica glass cracking mechanisms, it is necessary to correctly model the different features characterizing its mechanical behavior before fracture. Particularly, it is necessary to correctly model the densification process which is known to drastically modify the fracture behavior of this material [9, 27]. To

meet this need, a densification model based on the cohesive beam bonds between the discrete elements was recently developed in a previous paper [32]. Although it provides relatively good results in quasi-statics, this model involves a large number of calibration parameters, which makes the calibration procedure tedious and very time-consuming. Furthermore, it lacks flexibility and can only be applied in quasi-statics where silica glass densification presents a nearly linear evolution with pressure. However, its application to reproduce the complex densification features characterizing the silica glass response in highly dynamics is very challenging [31]. To overcome these limitations, the present paper proposes a new and very promising way to model silica glass densification under hydrostatic pressure. An accurate predictive-corrective densification model is proposed. As will be seen later, this model shows a great flexibility to reproduce extremely complex densification features. In addition, it is very easy to apply, since it involves only one calibration parameter.

Following this introduction, the present paper is divided into four sections. Section 2 gives a brief review of the variation of discrete element methods for continuous materials used in this work. Section 3 details the predictive-corrective densification model developed in the present paper to model silica glass densification under hydrostatic pressure. Section 4 tries to validate this model through its application to simulate the response of a silica glass sphere subjected to high hydrostatic compression. Section 5 presents some conclusions.

2. DISCRETE ELEMENT METHOD FOR CONTINUOUS MATERIALS

The variation of discrete element methods used in this work is that developed by André *et al.* [6, 7, 33, 34] to model continuous materials. For simplicity, this variation will simply be referred to as the discrete element method (DEM) in the remainder of this paper. This approach can be regarded as an “hybrid” approach between lattice methods [61, 62] and particle methods [19, 20]. A continuum is represented by a discrete domain having the same outside dimensions and made up of a set of rigid spherical discrete elements (particles). This discrete domain must satisfy several geometrical conditions to take into account the structural properties of the modeled continuum. For example, in the case of silica glass, two main structural properties must be considered: homogeneity and geometrical isotropy. According to several works in the literature [23, 25], homogeneity can be taken into account in the discrete domain by satisfying two criteria. The first criterion is concerned with the average coordination number n_{coord} (average number of discrete element neighbors) which must be larger than 6 [25]; and the second criterion is concerned with the volume fraction v_f (ratio of the volume occupied by the discrete elements to the total volume of the discrete domain) which must be larger than 0.63 [23]. To ensure the geometrical isotropy of the discrete domain, the directions of the contacts between each discrete element and its neighbors must be evenly distributed in the 3D space. André *et al.* [7, 33] have shown that the use of polydisperse discrete elements with a uniform radius distribution of $\chi = 25\%$ seems to guarantee the minimum required for the discrete domain to be considered as geometrically isotropic. Indeed, using polydisperse discrete elements, a highly irregular discrete domain can be obtained, with no preferential directions.

To ensure the cohesion of this domain, the adjacent discrete elements are connected by cylindrical cohesive beam bonds (fig. 1). This type of bonds seems to be the best adapted to model continua

using spherical particles. Indeed, both forces and torques are computed on the discrete elements, which makes it possible to properly consider shear effects in the modeled continuum. The contact detection procedure is only activated one time at the beginning of the simulation to detect the adjacent discrete elements that must be connected by cohesive beam bonds. During the simulation, the interaction between these elements is governed by the bonds, provided that there is no fracture. This permits significant computation time saving. When fracture takes place, an optimized contact process can be activated to deal with the interaction between the fractured elements and the remainder of the discrete domain. To compute the forces and torques in the cohesive beam bonds, the Euler–Bernoulli beam theory [65] is used:

$$\mathbf{F}_\mu^{DE1} = +E_\mu S_\mu \frac{\Delta l_\mu}{l_\mu} \mathbf{x} + \frac{6E_\mu I_\mu}{l_\mu^2} (-(\theta_{2z} + \theta_{1z})\mathbf{y} + (\theta_{2y} + \theta_{1y})\mathbf{z}) \quad (1)$$

$$\mathbf{F}_\mu^{DE2} = -E_\mu S_\mu \frac{\Delta l_\mu}{l_\mu} \mathbf{x} - \frac{6E_\mu I_\mu}{l_\mu^2} (-(\theta_{2z} + \theta_{1z})\mathbf{y} + (\theta_{2y} + \theta_{1y})\mathbf{z}) \quad (2)$$

$$\mathbf{T}_\mu^{DE1} = +\frac{G_\mu I_{O_\mu}}{l_\mu} (\theta_{2x} + \theta_{1x})\mathbf{x} - \frac{2E_\mu I_\mu}{l_\mu} ((\theta_{2y} + 2\theta_{1y})\mathbf{y} + (\theta_{2z} + 2\theta_{1z})\mathbf{z}) \quad (3)$$

$$\mathbf{T}_\mu^{DE2} = -\frac{G_\mu I_{O_\mu}}{l_\mu} (\theta_{2x} + \theta_{1x})\mathbf{x} - \frac{2E_\mu I_\mu}{l_\mu} ((2\theta_{2y} + \theta_{1y})\mathbf{y} + (2\theta_{2z} + \theta_{1z})\mathbf{z}) \quad (4)$$

Where:

- $R(\mathbf{x}, \mathbf{y}, \mathbf{z})$ is the beam local frame where \mathbf{x} is the beam axis (fig. 1).
- $R(\mathbf{x}_1, \mathbf{y}_1, \mathbf{z}_1)$ and $R(\mathbf{x}_2, \mathbf{y}_2, \mathbf{z}_2)$ are local frames associated with the discrete elements 1 and 2.
- \mathbf{F}_μ^{DE1} and \mathbf{F}_μ^{DE2} are the beam force reactions acting on the discrete elements 1 and 2 (connected to this beam bond).
- \mathbf{T}_μ^{DE1} and \mathbf{T}_μ^{DE2} are the beam torque reactions acting on the discrete elements 1 and 2.
- l_μ and Δl_μ are the initial beam length and the longitudinal extension.
- $\boldsymbol{\theta}_1(\theta_{1x}, \theta_{1y}, \theta_{1z})$ and $\boldsymbol{\theta}_2(\theta_{2x}, \theta_{2y}, \theta_{2z})$ are the rotations of the beam cross sections expressed in the beam local frame.
- S_μ , I_{O_μ} and I_μ are respectively the beam cross-sectional area, the polar moment of inertia and the second moment of area with respect to the \mathbf{y} and \mathbf{z} axes.
- E_μ and G_μ are respectively the Young's and shear moduli.

The microscopic quantities (of the cohesive beam bonds) are subscripted with “ μ ” to be distinguished from the macroscopic ones (of the material being modeled) that are subscripted with “ M ” hereafter.

The numerical resolution of the DEM system of equations is performed using the velocity Verlet scheme which is an explicit integration scheme [58]. The discrete element position \mathbf{p} and velocity $\dot{\mathbf{p}}$ are estimated from the linear acceleration $\ddot{\mathbf{p}}$ as follows:

$$\begin{aligned} \mathbf{p}(t + \Delta t) &= \mathbf{p}(t) + \Delta t \dot{\mathbf{p}}(t) + \frac{\Delta t^2}{2} \ddot{\mathbf{p}}(t) \\ \dot{\mathbf{p}}(t + \Delta t) &= \dot{\mathbf{p}}(t) + \frac{\Delta t}{2} [\ddot{\mathbf{p}}(t) + \ddot{\mathbf{p}}(t + \Delta t)] \end{aligned} \quad (5)$$

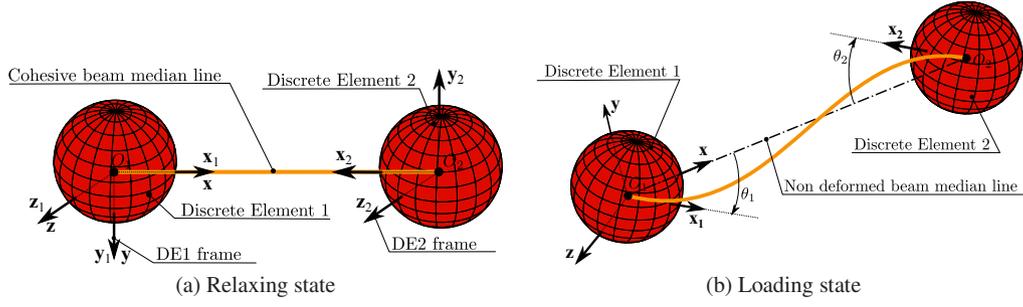

Figure 1. Cohesive beam bond between two discrete elements (Taken from [7])

where t and Δt are respectively the current time and the integration time step. In the present DEM variation, the discrete element orientations are described by quaternions, noted \mathbf{q} , which allow an efficient way to compute the rotation of the local frames associated with the discrete elements [52]. For more details on the use of quaternions, the reader is referred to references [5, 52]. The velocity Verlet scheme is also applied to the quaternions as follows:

$$\begin{aligned} \mathbf{q}(t + \Delta t) &= \mathbf{q}(t) + \Delta t \dot{\mathbf{q}}(t) + \frac{\Delta t^2}{2} \ddot{\mathbf{q}}(t) \\ \dot{\mathbf{q}}(t + \Delta t) &= \dot{\mathbf{q}}(t) + \frac{\Delta t}{2} [\ddot{\mathbf{q}}(t) + \ddot{\mathbf{q}}(t + \Delta t)] \end{aligned} \quad (6)$$

where $\dot{\mathbf{q}}$ and $\ddot{\mathbf{q}}$ are respectively the first and second time derivatives of \mathbf{q} . As for the linear acceleration, $\ddot{\mathbf{q}}$ is calculated using the Newton second law (angular momentum part) [5, 52]. To prevent \mathbf{q} numerical drift, the quaternion must be normalized at each time step. Algorithm 1 presents the resolution steps of the DEM calculation using the velocity Verlet scheme [7].

Equations (1), (2), (3) and (4) involve several microscopic parameters that must be determined so as to ensure the expected macroscopic elastic behavior of the considered continuum, some of which are interdependent. Based on the works of André *et al.* [7, 33], only two independent microscopic parameters influence the macroscopic elastic behavior: the dimensionless radius \tilde{r}_μ (defined as the ratio of the beam radius to the average particle radius) and the microscopic Young's modulus E_μ . These parameters must be determined by calibration procedure using discrete domains prepared in such a way as to satisfy the geometrical conditions dictated by the structural properties of the modeled continuum, as explained above. Furthermore, these domains must be constructed using at least $n_{DE} = 10\,000$ discrete elements. Indeed, André *et al.* [7] have demonstrated in their study that, for a given set of microscopic parameters (\tilde{r}_μ, E_μ), the resulting macroscopic elastic behavior (of the modeled domain) depends upon the number of discrete elements up to approximately $n_{DE} = 10\,000$ (fig. 2). Beyond this value, the macroscopic elastic properties converge towards limit values (*i.e.* the macroscopic behavior becomes nearly independent of n_{DE}). Therefore, to minimize the influence of n_{DE} on the calibrated values of the microscopic parameters, discrete domains made up of at least $n_{DE} = 10\,000$ discrete elements must be used in the calibration procedure. To simplify this procedure, micro-macro relationships relating the microscopic parameters (E_μ and \tilde{r}_μ) to the macroscopic elastic properties (E_M and ν_M) were determined numerically, using numerical samples having the following geometrical settings: average coordination number $n_{coord} = 13.2$, volume fraction $v_f = 0.68$, uniform radius distribution $\chi = 25\%$ and number of discrete elements $n_{DE} = 10\,000$. These relationships take the following forms:

$$\begin{aligned}\tilde{r}_\mu &= f(\nu_M) \\ E_\mu &= g(\tilde{r}_\mu) E_M\end{aligned}\tag{7}$$

where f and g are polynomials. Unless otherwise specified, the geometrical settings used to obtain the micro-macro relationships will be held to construct all the discrete domains that will be used in the remainder of the present paper. Using these relationships, table I presents the calibrated values of E_μ and \tilde{r}_μ corresponding to silica glass.

Silica glass macroscopic properties	$E_M = 72\text{ GPa}$	$\nu_M = 0.17$
Beam bonds microscopic properties	$E_\mu = 129\text{ GPa}$	$\tilde{r}_\mu = 0.6$

Table I. Silica glass mechanical properties and the associated calibrated microscopic parameters

Using the microscopic parameters of table I, it is now possible to model the macroscopic elastic behavior of silica glass. The next section deals with the development of an accurate model to describe the densification behavior of this material which is assumed to occur only under hydrostatic pressure.

3. MODELING OF DENSIFICATION UNDER HYDROSTATIC PRESSURE

As seen in the previous section, the DEM variation used in this work models a continuum by a set of rigid spherical particles linked with cohesive beam bonds which model the mechanical behavior of the studied material. Therefore, the natural way to model permanent deformation with this method

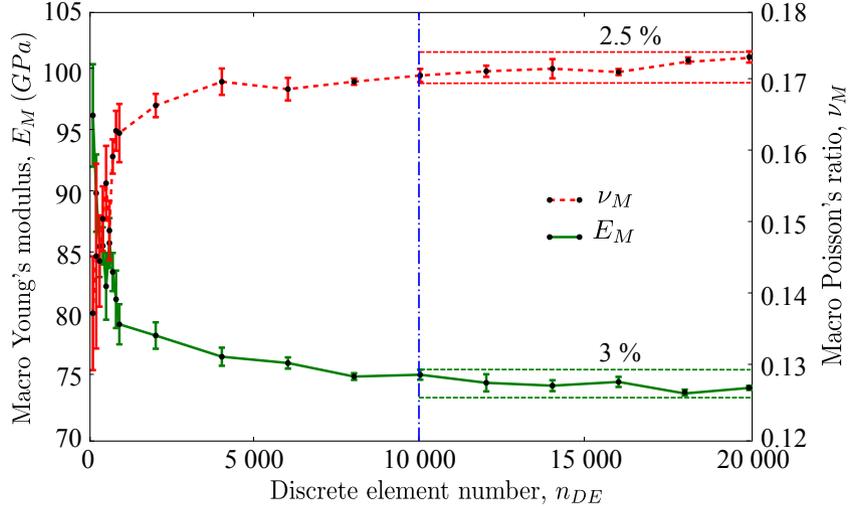

Figure 2. Evolution of the macroscopic elastic properties E_M and ν_M as a function of the number of discrete elements, for given microscopic beam bond parameters (taken from [7]).

is to enrich these bonds to take into account such phenomenon. Almost all the models proposed in the literature to model permanent deformation with DEM are based on this way [31, 32, 64]. Although these models were successfully applied to simulate permanent deformation of several materials, they suffer from several difficulties. Indeed, they generally involve a large number of calibration parameters, which makes the calibration procedure very challenging. Furthermore, they can only be applied on materials for which the permanent deformation behavior is relatively simple. To overcome these difficulties, the present section proposes a new approach to model permanent deformation of materials with the discrete element method. More specifically, this approach is developed to model densification of materials, *e.g.* silica glass, under hydrostatic pressure.

The key idea behind this new approach is that, in the framework of traditional continuum methods, several techniques have already been proposed and successfully applied to model complex mechanical behaviors. Therefore, it would be beneficial to apply these techniques for the discrete element method. However, to achieve this aim, it is necessary to establish relationships between certain microscopic (of discrete elements) and macroscopic (of continua) quantities, allowing for discrete-continuum bridging. Pioneering work in this respect has been done by Born and Huang [11] who have used an elastic energy approach to evaluate the stress in lattices by means of the Cauchy-Born hypothesis for homogeneous deformation. Subsequently, other formulations have been proposed to calculate the stress in molecular dynamics (MD). Chief among them is the virial stress which is a generalization of the virial theorem of Clausius (1870) for gas pressure. This formulation has become very popular and widely used in different discrete methods [28]. Therefore, it is retained in this work to bridge the discrete and continuum mechanics in order to develop the new densification model.

3.1. Virial stress

3.1.1. Formulation As originally established [48], the expression of virial stress includes two parts: the first part depends on the mass and velocity (or, in some versions, velocity fluctuation)

of the particles; the second part, which provides a continuum measure of the internal mechanical interactions between particles, depends on the inter-particle forces and the particle positions. Using this expression, the average virial stress over a volume Ω around a particle i is given by:

$$\bar{\Pi} = \frac{1}{\Omega} (-m_i \dot{\mathbf{u}}^i \otimes \dot{\mathbf{u}}^i + \frac{1}{2} \sum_{j \neq i} \mathbf{l}^{ij} \otimes \mathbf{f}^{ij}) \quad (8)$$

where m_i and $\dot{\mathbf{u}}_i$ are respectively the mass and velocity of the particle i , $\mathbf{l}^{ij} = \mathbf{l}^j - \mathbf{l}^i$ is the vector from particle i to particle j , \mathbf{l}^i is the position vector of particle i , \mathbf{f}^{ij} is the inter-particle force exerted by particle j on particle i , and \otimes denotes the tensor product. Expression (8) has been used to compute the stress in discrete systems. Recently, Zhou [72] has demonstrated that this quantity is not a measure for mechanical forces between material points and cannot be regarded as a measure of a mechanical stress. This author has proposed another formulation to compute the average mechanical stress, including only the second part of (8). In a region of volume Ω around a particle i , the average stress is given by:

$$\bar{\sigma} = \frac{1}{2\Omega} \sum_{i \in \Omega} \sum_{j \neq i} \mathbf{l}^{ij} \otimes \mathbf{f}^{ij} \quad (9)$$

This expression (9) was developed for molecular dynamics (MD), where the inter-particle forces are only derived from a pair potential $\Phi(\mathbf{l}^{ij})$ and the distance between particles $l^{ij} = \|\mathbf{l}^{ij}\|$:

$$\mathbf{f}^{ij} = \frac{\partial \Phi(\mathbf{l}^{ij})}{\partial l^{ij}} \frac{\mathbf{l}^{ij}}{l^{ij}} \quad (10)$$

In this case, the resulting stress tensor would be symmetric. However, this cannot be generalized to all other discrete methods. Several papers studying the symmetry of the equivalent stress tensor (obtained using different techniques) in discrete systems can be found in the literature [2, 10, 15, 30]. Based on these papers, in a general case, the symmetry of such a tensor can only be guaranteed when the inter-particle forces \mathbf{f}^{ij} are parallel to the vectors linking the particle centers \mathbf{l}^{ij} . This is particularly true when the particles are linked by spring bonds. This problem is due to the limitations of the existing techniques used in the framework of discrete systems to assess this tensor, which lack accuracy. Further research effort is needed in this direction to get over these limitations. The DEM variation used in this work, where the inter-particle forces are computed based on the cohesive beam bonds, does not guarantee the symmetry of the obtained tensor, although the non-symmetric effects are generally small. A solution to obtain a quasi-symmetric stress tensor with this approach is to assess this tensor by averaging over a large volume that contains a sufficient number of discrete elements. However, this solution makes the calculation of such a tensor very time-consuming and can strongly affect the robustness of any densification model based on this solution. In the present work, a symmetrized form of (9) is used to compute the average stress in a region Ω around a discrete element i :

$$\bar{\sigma} = \frac{1}{2\Omega} \sum_{i \in \Omega} \sum_{j \neq i} \frac{1}{2} (\mathbf{l}^{ij} \otimes \mathbf{f}^{ij} + \mathbf{f}^{ij} \otimes \mathbf{l}^{ij}) \quad (11)$$

This solution, which is used in the literature to quickly assess an equivalent stress tensor in discrete systems [8, 32, 66], generally provides a fair compromise between accuracy and computation cost. Based (11), a Cauchy-like stress tensor can be approximated in each discrete element i as follows:

$$\boldsymbol{\sigma}^i = \frac{1}{2\Omega_i} \sum_{j=1}^{n_i} \frac{1}{2} (\mathbf{l}^{ij} \otimes \mathbf{f}^{ij} + \mathbf{f}^{ij} \otimes \mathbf{l}^{ij}) \quad (12)$$

where n_i is the number of the discrete elements connected to particle i and Ω_i is an effective volume associated to this particle. The spherical part of this tensor ($P_{num}^i = \frac{1}{3} tr(\boldsymbol{\sigma}^i)$) will be used to develop the densification model. Note that this part and then the densification model that will be developed are not influenced by the symmetrization of the stress tensor. The question that arises here is how to choose the effective volumes of the discrete elements so as to ensure that the numerical pressure P_{num}^i in a discrete element i is equal to the real pressure in this element. The next subsection tries to answer this question.

3.1.2. Choice of the effective volume of the discrete elements Since the present work deals with the modeling of densification under hydrostatic pressure, the choice of the effective volumes to be assigned to the discrete elements will be performed taking into account only the spherical part of the Cauchy-like stress (12). These volumes must be determined in such a way as to ensure equality between the numerical pressure computed using (12) and the true pressure in the discrete elements. Due to lack of theoretical basis, there is no analytical approach allowing for obtaining such volumes in a simple and effective manner. The present subsection proposes to investigate this task numerically. Various proposals of effective volumes will be tested using a spherical specimen of 100 mm diameter subjected to hydrostatic pressure. This specimen is discretized using 10 000 discrete elements. The same microscopic parameters as those presented in table I are used to model the elastic behavior of the specimen. To evaluate each proposal of effective volume, the evolution of the numerical pressure in the specimen as a function of the specimen volume change will be plotted and commented. To minimize numerical fluctuations, average pressure computed using all the specimen discrete elements (or in some cases using the boundary discrete elements to study the boundary effects) will be used instead of individual discrete element pressures. In the following, the average pressure obtained using all the specimen discrete elements will be referred to as “specimen numerical pressure” and that obtained using only the boundary discrete elements will be referred to as “boundary numerical pressure”.

First, the volume occupied by each discrete element i , which is constant, is chosen to be the effective volume of this element Ω_i^s (fig. 4):

$$\Omega_i^s = \frac{4}{3} \pi r_i^3 \quad (13)$$

where r_i is the radius of the discrete element i . Using (13), figure 3 presents the evolution of the specimen numerical pressure with the specimen volume change. To investigate the boundary effects, the evolution of the boundary numerical pressure with the specimen volume change is also presented in this figure. Using constant effective volumes, nonlinear dependence between the numerical pressures and the specimen volume change is obtained, which makes no mechanical sense. Furthermore, there is a relatively large difference between the numerical pressure calculated using all the discrete elements and that calculated using only the boundary discrete elements.

To overcome the problem of nonlinearity, it is necessary to take into account the variation of the effective volumes of the discrete elements with pressure. To this end, the effective volume of each

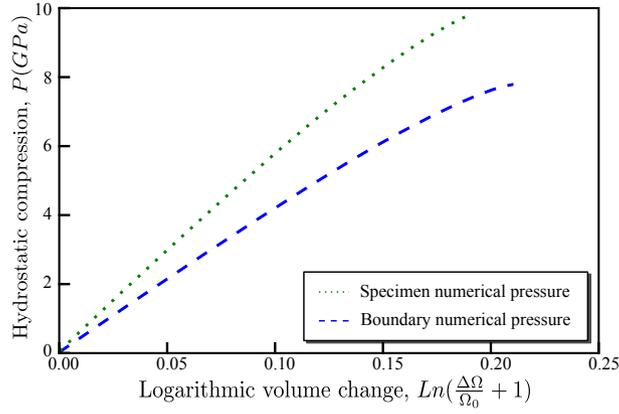

Figure 3. Evolution of the specimen numerical pressure and the boundary numerical pressure with the specimen volume change for constant effective volumes

discrete element i is chosen to be the volume of a sphere having as radius (r_i^v) half the average length of the cohesive beam bonds connected to this element (fig. 4):

$$\Omega_i^v = \frac{4}{3} \pi (r_i^v)^3 \quad \text{with} \quad r_i^v = \frac{1}{n_i} \sum_{j=1}^{n_i} \frac{l^{ij}}{2} \quad (14)$$

where n_i is the number of the beams connected to the discrete element i and l^{ij} is the length of the beam linking discrete elements i and j . Since the beam lengths vary with the applied pressure, the effective volumes will vary accordingly. Using (14), figure 5 shows the evolution of the specimen and the boundary numerical pressures with the specimen volume change. The use of variable effective volumes corrects the problem of nonlinear dependence between the numerical pressure and the specimen volume change. However, it does not help to reduce the boundary effects which underlie an underestimation of the numerical pressure computed using only the boundary discrete elements (fig. 5).

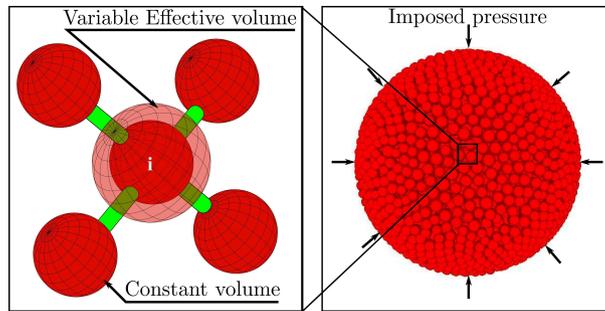

Figure 4. Variable effective volumes of the discrete elements

To reduce these effects, it is necessary to correct the effective volumes of the boundary discrete elements so as to take into account their truncation by the specimen boundary (fig. 6). However, this issue is not straightforward. Indeed, it requires prior knowledge of the precise positioning of these elements with respect to the boundary which is generally difficult to draw. To alleviate this problem, the effective volume of each discrete element i (14) is multiplied by a boundary correction parameter c_i^b defined as the ratio between the number of the cohesive beams bonds connected to

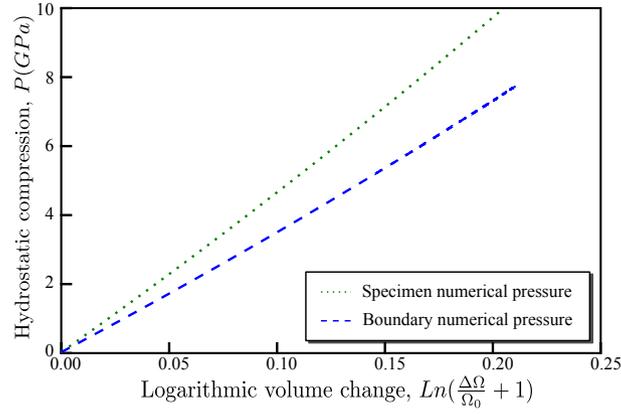

Figure 5. Evolution of the specimen numerical pressure and the boundary numerical pressure with the specimen volume change for variable effective volumes

this element (n_i) and the average number of the cohesive beam bonds connected to internal discrete elements (n_{mean}):

$$\Omega_i^b = c_i^b \times \Omega_i^v \quad \text{with} \quad c_i^b = \frac{n_i}{n_{mean}} \quad (15)$$

Figure 6 illustrates schematically the influence of this parameter. It should be noted that, for internal discrete elements, c_i^b is close to 1 ($c_i^b \approx 1$). Applying (15), the difference between the numerical pressure obtained using all the discrete elements and the numerical pressure obtained using only the boundary discrete elements is considerably reduced (fig. 7). An error of less than 3% is noted between these pressures. This error could be acceptable, especially a few number of discrete elements (only those belonging to the boundary) are affected by it.

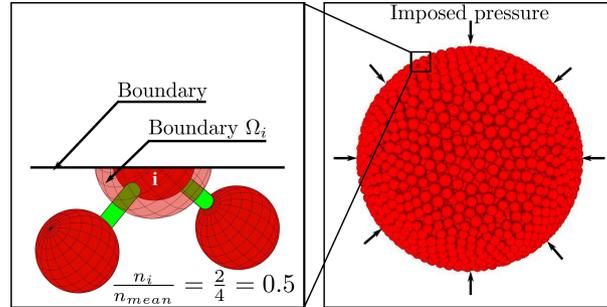

Figure 6. Variable effective volumes of the discrete elements with boundary correction

In the above paragraphs, the effective volumes of the discrete elements are corrected so as to alleviate numerical difficulties related to the boundary effects and the nonlinear pressure dependence of the volume change. The question that arises here is whether the numerical pressure obtained using these corrections would accurately represent the real pressure. To answer this question, the specimen numerical pressure computed using (15) is compared with the hydrostatic pressure imposed on the specimen (fig. 7). An error of approximately 9% is found between the pressures. Since the densification model that will be proposed in the following is based on the pressures in discrete elements, this error must be reduced to ensure a correct functioning of this model. A potential source of such error could be the definition of the effective volumes which should again be corrected to

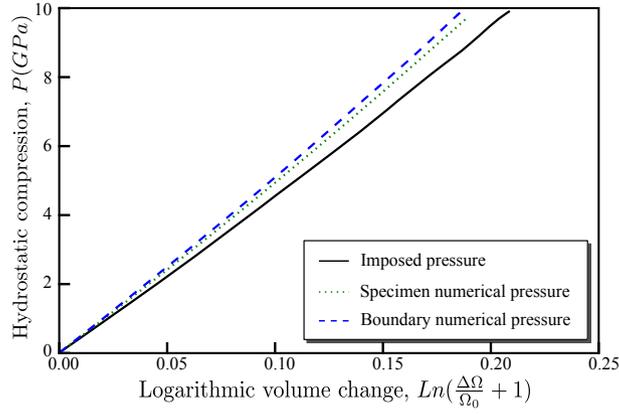

Figure 7. Evolution of the specimen numerical pressure and the boundary numerical pressure with the specimen volume change for variable effective volumes with boundary correction

take into account shape irregularity. A final correction is then made to the definition of the effective volumes by multiplying their expressions (15) by a parameter c which is the same for all the discrete elements:

$$\Omega_i^c = c \times \Omega_i^b \quad (16)$$

The parameter c has to be determined by calibration and can be interpreted as a shape correction parameter that takes into account the shape irregularity of the effective volumes. It is the only one calibration parameter, very easy to calibrate, of the densification model that will be developed in the following. To obtain this parameter, it is sufficient to simulate the response of an elastic numerical sample subjected to hydrostatic pressure, while using $c = 1$. The right value of c is simply the ratio of the specimen numerical pressure to the imposed pressure. The right value of c corresponding to silica glass can be determined using figure 7: $c = 1.09$. Figure 8 compares the specimen numerical pressure obtained using this value with the imposed pressure. These pressures are in very close agreement, which proves the validity of the calibrated value of the shape correction parameter c .

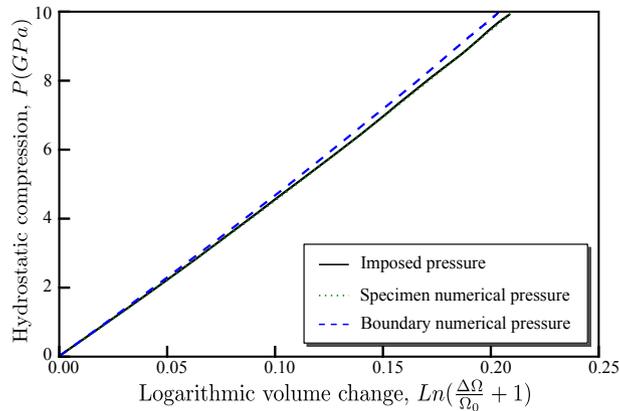

Figure 8. Comparison between the specimen numerical pressure and the hydrostatic pressure imposed on this specimen after shape correction of the effective volumes ($c = 1.09$)

One major issue generally encountered in discrete methods is that the calibration parameters can depend upon the number of the discrete elements (n_{DE}) used to discretize the numerical sample. The influence of this number on the calibration of the shape correction parameter c must then be studied. To this end, the same numerical test of spherical specimen under hydrostatic pressure is used with different n_{DE} (from 2 000 to 18 000). Figure 9 presents the associated calibration results. Beyond $n_{DE} = 10\,000$, the calibrated value of c becomes very weakly affected by the discrete element number. This result is in accordance with the results of André *et al.* [7] who have shown that beyond $n_{DE} = 10\,000$ the microscopic elastic parameters determined by calibration become nearly independent of n_{DE} .

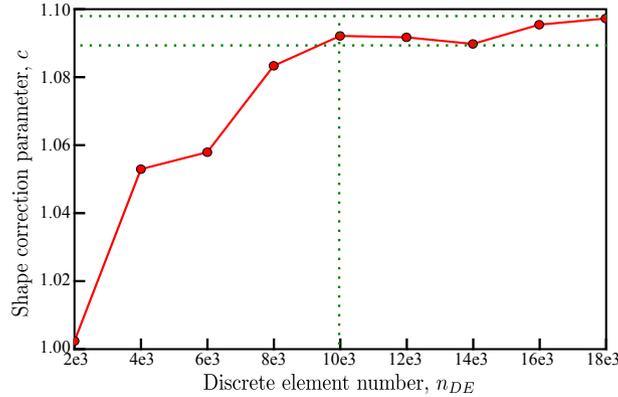

Figure 9. Variation of the shape correction parameter c with the number of the discrete elements used to discretize the numerical sample

In summary, the effective volume that must be assigned to each discrete element i to ensure the equivalence between the numerical pressure and the real pressure in this element is defined as follows:

$$\Omega_i^c = \frac{4}{3} \pi c \frac{n_i}{n_{mean}} \left(\frac{1}{n_i} \sum_{j=1}^{n_i} l^{ij} \right)^3 \quad (17)$$

where c is a calibration parameter, n_i is the number of the cohesive beams bonds connected element i , n_{mean} is the average number of the cohesive beam bonds connected to internal discrete elements, and l^{ij} is the length of the cohesive beam bond linking elements i and j . Using this definition, it would be possible to approximate the pressure in the discrete elements. This opens the floodgates to a new way to model densification with the discrete element method as will be seen in the following subsection.

3.2. Predictive-corrective technique to model densification

Based on (12) and (17), a new densification model inspired by the “predictive-corrective” technique for plasticity is developed (fig. 10). At each time step, the volume change ($\Delta\Omega_i^c/\Omega_{i0}^c$, with $\Delta\Omega_i^c = \Omega_i^c - \Omega_{i0}^c$ and Ω_i^c and Ω_{i0}^c are respectively the current and initial effective volumes of a discrete element i) and the numerical pressure (P_{num}^i) in each discrete element i can be approximated using respectively (17) and (12). Based on a given (for example experimentally measured) curve of pressure versus volume change (fig. 10), the expected pressure in the discrete element i (P_{exp}^i) corresponding to $\Delta\Omega_i^c/\Omega_{i0}^c$ can be determined and compared to P_{num}^i . If $\Delta P_{num}^i = P_{exp}^i - P_{num}^i$

is nonzero, the pressure difference (ΔP_{num}^i) must be returned to the DEM system. However, this is not as simple as one might think because this quantity (in its pressure form) cannot directly be considered in the DEM computation which only supports forces and torques. To achieve this aim, it is necessary to convert ΔP_{num}^i into correction forces to be injected in the cohesive beam bonds linking the discrete element i to its neighbors. The following derivation shows how this can be possible.

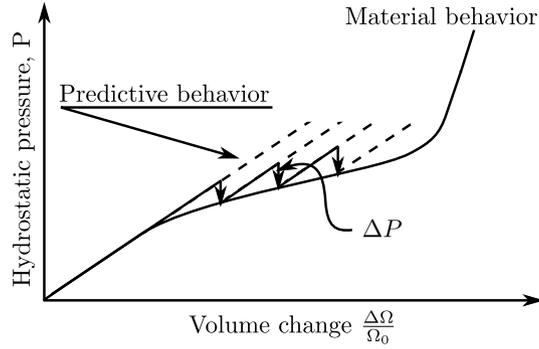

Figure 10. Predictive-Corrective densification model

Since the numerical pressure P_{num}^i in a discrete element i is expressed:

$$P_{num}^i = \frac{1}{3} (\sigma_{11}^i + \sigma_{22}^i + \sigma_{33}^i)$$

where σ^i is the stress tensor computed in the discrete element i , ΔP_{num}^i can also be expressed as follows:

$$\Delta P_{num}^i = \frac{1}{3} (\Delta \sigma_{11}^i + \Delta \sigma_{22}^i + \Delta \sigma_{33}^i) \quad (18)$$

To avoid numerical problems, each $\Delta \sigma_{kk}^i$ ($k \in [1, 2, 3]$) must satisfy:

$$\frac{\Delta \sigma_{kk}^i}{\Delta P_{num}^i} = \frac{\sigma_{kk}^i}{P_{num}^i} \quad (19)$$

Using (19), the correction part of each diagonal term of the stress tensor can be determined. In a similar way, $\Delta \sigma_{kk}^i$ can be expressed as:

$$\Delta \sigma_{kk}^i = \sum_{j=1}^{n_i} \Delta \sigma_{kk}^{ij} \quad (20)$$

where n_i is the number of discrete elements connected to i and σ_{kk}^{ij} is the contribution of the cohesive beam bond connecting the discrete element i to the discrete element j in the computation of σ_{kk}^i . Each $\Delta \sigma_{kk}^{ij}$ must also satisfy:

$$\frac{\Delta \sigma_{kk}^{ij}}{\Delta \sigma_{kk}^i} = \frac{\sigma_{kk}^{ij}}{\sigma_{kk}^i} \quad (21)$$

Knowing (21), it is possible to determine Δf^{ij} that must be introduced in the cohesive beam bond between the discrete elements i and j :

$$\Delta f_k^{ij} = \frac{2 \Omega_i^c \Delta \sigma_{kk}^{ij}}{l_k^{ij}} \quad k \in [1, 2, 3] \quad (22)$$

l^{ij} is the oriented length of the beam linking the particles i and j and Ω_i^c is effective volume of the discrete element i (17). Keeping in mind equations (19) and (21), equation (22) can be simplified as follows:

$$\Delta f^{ij} = \frac{\Delta P_{num}^i}{P_{num}^i} f^{ij} \quad (23)$$

The last expression translates ΔP_{num}^i into correction forces supported by the discrete system and makes it possible to correct the current mechanical state of the considered discrete element. This is the last step of the “predictive-corrective” densification model proposed in this work. This model presents a great flexibility to reproduce very complex densification behaviors with only one calibration parameter. The next section attempts to apply this model to simulate the densification behavior of silica glass under hydrostatic pressure.

4. APPLICATION: HYDROSTATIC COMPRESSION OF SILICA GLASS

As mentioned in the introduction, silica glass can densify under high hydrostatic pressures. Based on references [36, 38, 59], the densification behavior of this material takes place between approximately 8 GPa and 20 GPa, at which the permanent volume change can reach 17.4%. Figure 11 shows the silica glass mechanical behavior under hydrostatic pressure, which is inferred from ex-situ experimental results collected in reference [40]. During this process, the Young’s modulus and the Poisson’s ratio increase with the applied hydrostatic pressure (fig. 12). At the end of densification, these properties show an augmentation of respectively 46% and 56%.

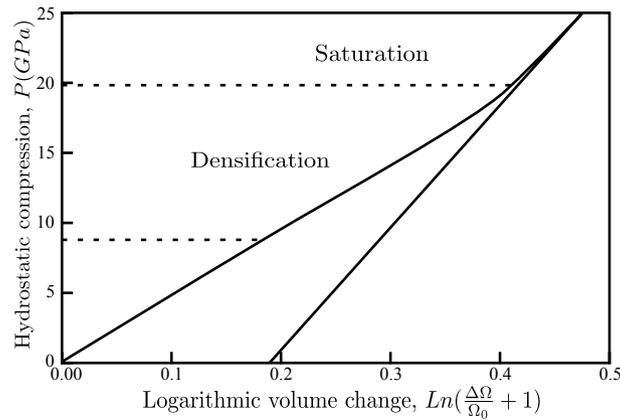

Figure 11. Silica glass behavior under hydrostatic pressure (inferred from the experimental results collected in reference [40])

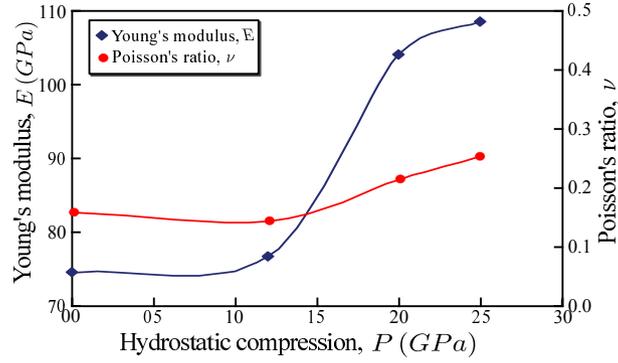

Figure 12. Variation of the silica glass mechanical properties with pressure (taken from [36])

The present section aims to simulate the silica glass densification behavior as well as the associated mechanisms, using the proposed predictive-corrective model. A silica glass sphere of 100 mm diameter is used in this simulation. This sphere is constructed using the same geometrical settings as presented in section 2 and discretized using 20 000 discrete elements. The microscopic elastic parameters of the cohesive beam bonds corresponding to silica glass are given in table I. The shape correction parameter that corresponds to silica glass is $c = 1.09$. The densification curve presented in figure 11 is used as reference curve on which the mechanical state of each discrete element is projected at every time step. Concerning the variation of the silica glass mechanical properties during densification, it is assumed for simplicity in this work that these properties evolve linearly with the applied pressure in the region of densification and remain constant everywhere else (fig. 12). Using this assumption, it is very easy to take into account such variation with the proposed predictive-corrective model. For each time step, the hydrostatic pressure in each discrete element i (P_{num}^i) is assessed using (12). If $8 \text{ GPa} \leq P_{num}^i \leq 20 \text{ GPa}$, this pressure is first corrected to become equal to the expected pressure in this element ($P_{num}^i = P_{exp}^i$). Then, the macroscopic mechanical properties associated to P_{exp}^i are determined using figure 12. Finally, the corresponding microscopic properties (E_{μ}^i and \tilde{r}_{μ}^i) are calculated using (7). By doing so, the elastic parameters of a cohesive beam bond linking elements i and j can be determined and updated as follows:

$$E_{\mu}^{ij} = \frac{E_{\mu}^i + E_{\mu}^j}{2} \quad \text{and} \quad \tilde{r}_{\mu}^{ij} = \frac{\tilde{r}_{\mu}^i + \tilde{r}_{\mu}^j}{2} \quad (24)$$

Taking into account the variation of the mechanical properties with densification, figure 13 presents the response of the silica glass sphere subjected to high hydrostatic compression. The numerical response compares very favorably with the reference one, which means that the developed predictive-corrective model faithfully reproduces the silica glass mechanical behavior. To analyze the evolution of the densification level with the applied pressure, the silica glass sphere is subjected to different hydrostatic pressures. The associated permanent volume changes measured after relaxation are presented in figure 14. The numerical results are in very close agreement with the experimental ones obtained by Rouxel *et al.* [59] and Deschamps *et al.* [22]. These results are much better than other numerical results obtained in a previous paper [32] using a beam-based densification model. The numerical results obtained in this section shows the great ability of the developed predictive-corrective densification model to simulate the nonlinear mechanical behavior

of silica glass, with only one calibration parameter. This model will be used in a future work to study the behavior of silica glass in highly dynamics.

5. CONCLUSION

The present paper dealt with the development of a densification model adapted for DEM to simulate the nonlinear mechanical behavior of silica glass under hydrostatic pressure. This model is based on the computation of a Cauchy-like stress in the discrete elements using a modified expression of the virial stress which is widely used in the literature to assess the stress in discrete systems. One major difficulty in application of this expression to compute the stress in the discrete elements is related to the choice of the effective volumes of these elements. To get over this difficulty, various

proposals of effective volumes were numerically studied. Based on this study, variable effective volumes were retained to ensure linear dependence between the pressure and the volume change in the region of elasticity. The effective volume of each discrete element is chosen to be a sphere having as radius half the average length of the cohesive beam bonds connected to this element. This volume is multiplied by two correction parameters: boundary correction parameter and shape correction parameter. The first parameter is calculated by dividing the number of the cohesive beam bonds connected the considered discrete element by the average number of the cohesive beam bonds connected to internal discrete elements. The second parameter is determined by calibration. After determining this parameter, it is possible to assess the Cauchy-like stress, and then the hydrostatic pressure, in a given discrete element. Using the hydrostatic pressures in the discrete elements, a new densification model inspired by the predictive-corrective technique for plasticity is developed. The mechanical state in each discrete element, given in terms of volume change versus hydrostatic pressure, is determined and corrected with respect to a reference state. To validate this model, it was applied to simulate the silica glass densification behavior which is assumed to occur only under hydrostatic pressure. The associated numerical results are in very close agreement with the experimental results, which proves the effectiveness of the proposed model. Since only one calibration parameter is involved in this model, it is very easy to apply. This new model represents a major step towards accurate modeling of materials permanent deformation with the discrete element method. In a future work, it will be extended to model plasticity of crystalline solids.
