Experimental characterization of post rigor mortis human muscle subjected to small tensile strains and application of a simple hyper-viscoelastic model

Laure-Lise Gras^{1,2,3,4}, Sébastien Laporte¹, Philippe Viot⁵ and David Mitton^{2,3,4}

Abstract

In models developed for impact biomechanics, muscles are usually represented with one-dimensional elements having active and passive properties. The passive properties of muscles are most often obtained from experiments performed on animal muscles, because limited data on human muscle are available. The aim of this study is thus to characterize the passive response of a human muscle in tension. Tensile tests at different strain rates (0.0045, 0.045, and 0.45 s^{-1}) were performed on 10 *extensor carpi ulnaris* muscles. A model composed of a nonlinear element defined with an exponential law in parallel with one or two Maxwell elements and considering basic geometrical features was proposed. The experimental results were used to identify the parameters of the model. The results for the first- and second-order model were similar. For the first-order model, the mean parameters of the exponential law are as follows: Young's modulus E (6.8 MPa) and curvature parameter α (31.6). The Maxwell element mean values are as follows: viscosity parameter η (1.2 MPa s) and relaxation time τ (0.25 s). Our results provide new data on a human muscle tested in vitro and a simple model with basic geometrical features that represent its behavior in tension under three different strain rates. This approach could be used to assess the behavior of other human muscles.

Keywords

Biomechanics, human muscle, strain rate, tensile test, Maxwell model

Introduction

Different muscle models have been developed in the impact biomechanics field. Some are finite element models with constitutive laws defined to describe both the passive and active responses of the muscles in three dimensions.^{1–4} For instance, Behr et al.¹ proposed a finite element model of a muscle that takes into account the effect of muscle's fibers. However, even though the trend is to implement three-dimensional (3D) finite element models, muscles are still often described in most of the human body models as one-dimensional (1D) elements with specific properties.^{5–11} The muscles are usually modeled with Hill's model. This model has passive and active properties, and its passive mechanical properties are obtained from experiments on animal muscles and implemented in the human body models.

The passive response of muscles has been widely studied with experiments performed on muscle in

compression^{12–19} or tension.^{20–29} However, most of these experiments have been performed on animal muscles. Very few experiments have been conducted on human muscles in vitro in compression^{14,30,31} and tension.^{32–34} Even if animal data are considered for human body models, high variability is noted in the

experimental results presented in the literature. For instance, at the fiber level, Mutungi and Ranatunga³⁵ found a Young's modulus of around 1 MPa for slow fibers and around 0.1 MPa for fast fibers of rats' muscles, while Lieber et al.³⁶ evaluated a Young's modulus of 462.5 MPa for human muscle fibers. These results suggest that differences between human and animal muscle tissue exist. Therefore, it seems relevant to study human muscle tissue in vitro, even though such studies imply limitations such as testing fairly old and not fresh tissue.

Moreover, muscle mechanical properties differ from one muscle to another in a same subject.^{34,37} Indeed, Best et al.³⁷ who studied two different muscles of the rabbit leg found a stress at 10% strain for the *tibialis anterior* that was 35% of the stress at the same strain level for the *extensor digitorum longus*. Even though results were normalized with global parameters common to both muscles, they show the difficulty in comparing data that depend on the muscle and also on the applied experimental conditions. These differences may be related to muscles' geometry, fiber composition, extracellular matrix (collagen), and so on. In order to identify which characteristic is more prevalent on muscle response, a first step would be to characterize different muscles and thus create a database of muscle mechanical properties.

Our group recently showed that the hyper-elastic tensile behavior of the human *sternocleidomastoideus* muscle can be described using a simple model (exponential) considering basic geometrical features (initial length and cross-sectional area).³² In addition to the hyper-elastic behavior, viscosity parameters have been added through a first- or second-order Maxwell model.³³ The parameters were identified using an inverse finite element method and a quasi-static tensile test followed by a load-relaxation test. The second-order model was more prone to characterize the viscoelastic response of the *sternocleidomastoideus*, but the first-order model still gave a good estimate of the muscle response.

These results were obtained for a specific muscle, age group, gender, and experimental protocol. In order to extend our knowledge on human muscle hyper-viscoelastic mechanical properties, the aim of this article was thus to evaluate the ability of the same simple hyper-viscoelastic model to characterize the response of another human muscle subjected to a different in vitro experimental protocol including various velocities.

Materials and methods

Muscle specimens

Ten *extensor carpi ulnaris* muscles were collected from the right and left forearms of five male subjects (mean age: 71.6 years) that were frozen 4 days after their death, that is, post rigor mortis, and slowly thawed at

4 °C before muscles were removed from the body. This specific muscle was considered because it is superficial and easily accessible. It is a pinnate muscle. The muscles were removed with their aponeurosis, tendons, and two ends of bone blocks. They were wrapped in gauzes soaked with physiological saline solution, vacuum-packed, and frozen at -20 °C. The muscles were slowly thawed for 12 h at 4 °C and then stored for 2 h at ambient temperature until the tests were conducted.

Tensile tests

The muscle extremities were casted in jaws with an epoxy resin (exothermic temperature below 50 °C) (Figure 1). The osseous proximal extremity of the muscle was encapsulated in the jaw. The distal extremity presented a large tendon. To limit its effect on the muscle's response, it was set in the resin. The muscle was placed vertically between the jaws, and care was taken to avoid muscle twisting. The set of the muscle and jaws was then placed on a servo-hydraulic testing machine (INSTRON[®] 8802, High Wycombe, UK) controlled in displacement.

After positioning, the muscle was in a slack state that corresponded to a no-load position, and then the muscle was elongated until a 5 N pre-load was reached. This load corresponded to 5% of the expected load at failure of the muscle that was determined from a series of preliminary tests conducted up to failure on the *extensor carpi ulnaris* muscle of three other human subjects. Then, cyclic tensile tests were applied to the muscle to reach a steady state (50 triangular cycles, total amplitude: 2 mm, frequency: 0.5 Hz). This pre-conditioning phase was close to the experimental protocol proposed by Best et al.,³⁷ Myers et al.,²⁶ and Noonan et al.²⁷ who preconditioned a *tibialis anterior* muscle of rabbit by applying 6 mm displacement (5% of the load at failure), 1 Hz haversine for 50 cycles. Moreover, Van Ee et al.³⁸ have shown that for muscles that were previously frozen, up to 50 cycles were required to have a mechanical stabilization of the load (less than 2% variation), and that this stabilization induced a more reproducible response of the muscle.

At the end of the pre-conditioning phase, the length l (mm) and cross-sectional area S (mm²) of the muscle were defined. Afterward, stretch ramps of 8 mm displacement were applied to the muscle. Each muscle was tested at three velocities: 1, 10, and 100 mm s⁻¹. The ramps at 1 and 10 mm s⁻¹ were applied in a random order, and then the test at 100 mm s⁻¹ was conducted. Owing to high-speed grips, constant speeds were imposed to the muscle during the whole tension phase. After each ramp test, the sample was released back to post-stabilization length at the same velocity. Between each test, a rest period of at least 5 min was maintained. A visual inspection of the muscle between each test ensured that tissue was not damaged at the macroscopic level. Displacement d (mm) was measured with a linear variable differential transformer (LVDT) sensor

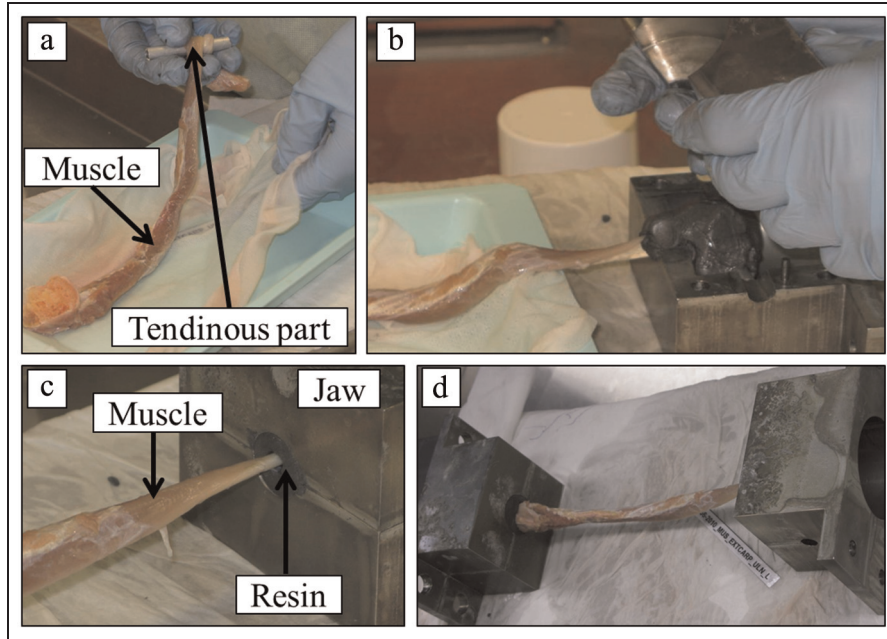

Figure 1. Protocol to place muscle in the jaws: (a) the muscle tendinous part is rolled around a screw, (b) muscle is placed in jaws and its extremity is casted with epoxy resin, (c) extremities are casted with epoxy resin, and (d) final result.

(accuracy of 1%), and load F (N) with a 1-kN sensor (accuracy of 0.5%). Over the 30-min duration of the test, the muscle was regularly moistened with physiological saline solution to avoid dehydration. No sliding of the specimen was observed during the experiments.

Muscle's geometrical parameters

Muscle's initial length l and initial cross-sectional area S were determined using two cameras placed in front of the muscle (Figure 2). Each camera gave one image of the muscle. The length l was measured on each image after the pre-load. Then, at the middle length of the

muscle, the width W was measured (Figures 2 and 3) from the same images. This parameter was used to calculate the cross-sectional area of the muscle. This area is assumed to be an ellipse

$$S = \pi ab \quad (1)$$

This assumption is based on a series of preliminary tests where muscles were scanned and whose cross section in the middle was approached by an ellipse. There was 1.8% error between the real area of the muscle and the area estimated with the ellipse.

The ellipse's parametric equation in the global reference space is

Figure 2. Top view of the position of the muscle on the testing machine and of the cameras in front of the muscle (distance and orientation angle θ), and definition of the coordinate systems (XY , and $x_c y_c$), length measured on the picture provided by the camera (W), and the parameters of the ellipsoid (a and b).

Figure 3. Measurements of the different lengths l and W obtained from the camera images. First, l is measured, and then at middle length, W is measured in pixels. These measurements are used to define the engineering strain and stress applied to each muscle.

$$X = a \cos(t); \quad Y = b \sin(t) \quad (2)$$

In the reference space of one camera, the projection along the abscissa is

$$x_c = a \cos(t) \cos(\theta) + b \sin(t) \sin(\theta) \quad (3)$$

with θ the inclination angle of the camera (15°). As a consequence, W is the length obtained when x_c is maximum, that is, when $\tan(t) = (b/a) \tan(\theta)$, and its expression is

$$\frac{W}{2} = [a^2 \cos^2(\theta) + b^2 \sin^2(\theta)]^{1/2} \quad (4)$$

The two images obtained from the cameras gave two measures of W , and with a nonlinear mean squares method, the parameters a and b were identified, and thus S . The cost function was

$$f = (1/2)^2 [W_{\text{Cam no.1}} - W_{\text{Theory}}]^2 + (1/2)^2 [W_{\text{Cam no.2}} - W_{\text{Theory}}]^2 \quad (5)$$

The conversion coefficients from pixel to meters were calculated using a reference length on the image. The method was validated using a cylinder of 200 mm length and 30 mm diameter. The mean error was 3.5%. For each muscle, the method was reproduced three times in a random order. The reproducibility error was less than 3%. The values chosen for l and S were the mean values of these three measurements. These parameters were used to obtain the engineering stress $\sigma_{\text{experiment}} = F/S$ (Pa) and strain $\varepsilon_{\text{experiment}} = d/l$ of the muscle's response.

Figure 4. Nonlinear viscoelastic model. The nonlinear element is defined with parameters E and α . The Maxwell element is defined with parameters E_M and η .

Statistical analysis

To assess the influence of velocity on muscle response, a statistical test was used on the maximum stress obtained from the experimental curves. The null hypothesis expressed the fact that velocity had no significant influence on the maximum stress. A risk of 5% was considered. As the number of tested muscles was small, and the results were paired, the Wilcoxon signed rank test for paired samples was used.

Nonlinear viscoelastic model

A nonlinear viscoelastic model was chosen to characterize the engineering stress–engineering strain of each muscle. This model is composed of a nonlinear element in parallel with one (first-order model) or two (second-order model) Maxwell elements (Figure 4). The nonlinear element response is defined by an exponential law as proposed by Sten–Knudsen³⁹

$$\sigma_{NL} = \frac{E}{\alpha} [\exp(\alpha \varepsilon_{\text{experiment}}) - 1] \quad (6)$$

where σ_{NL} is the stress for the nonlinear element (Pa), $\varepsilon_{\text{experiment}}$ is the strain ($\varepsilon_{\text{experiment}} = d/l$), E is a Young's modulus (Pa), and α is a curvature parameter (dimensionless).

The stress σ_M (Pa) in the Maxwell elements in tension is described as

$$\sigma_M = \sum_{i=1}^n \eta_i \dot{\varepsilon}_0 \left[1 - \exp\left(\frac{-t}{\tau_i}\right) \right] \quad (7)$$

where t is the time (s), $\dot{\varepsilon}_0$ is the constant applied strain rate depending on each muscle initial length, τ_i is the relaxation time (s), η_i is the viscosity (Pa s), and n is the number of Maxwell elements used in the model. The equivalent Young's modulus for this element is $E_M = \sum_{i=1}^n \eta_i / \tau_i$ (Pa). The global stress can be written as

$$\sigma_{\text{model}} - \sigma_0 = \sigma_{NL} + \sigma_M \quad (8)$$

where σ_0 (Pa) is the experimental stress just after the pre-load. The parameters of the model that have to be identified are E , α , η_i , and τ_i . These parameters were identified using MATLAB[®] R2008b software with a

nonlinear least-square method (function lsqnonlin, with the trust-region-reflective method); the cost function was

$$f = \frac{1}{n_1} [\sigma_{\text{experiment}}(v_1) - \sigma_{\text{model}}(v_1)]^2 + \frac{1}{n_{10}} [\sigma_{\text{experiment}}(v_{10}) - \sigma_{\text{model}}(v_{10})]^2 + \frac{1}{n_{100}} [\sigma_{\text{experiment}}(v_{100}) - \sigma_{\text{model}}(v_{100})]^2 \quad (9)$$

where $\sigma_{\text{experiment}}(v_1)$ is the experimental stress at 1 mm s^{-1} , and $\sigma_{\text{model}}(v_1)$ is the stress obtained according to equation (8) at 1 mm s^{-1} . The terms v_{10} and v_{100} refer to the 10 and 100 mm s^{-1} velocities, respectively, and n_1 , n_{10} , and n_{100} refer to the numbers of experimental points for each tensile test at each respective velocity. Therefore, the identified parameters depend on each muscle geometrical characteristics and applied strain rates. During optimization, initial parameters were necessary. They were the same for all the tested muscles and for both the first- and second-order models: $E_{\text{init}} = 10 \text{ MPa}$, $\alpha_{\text{init}} = 50$, $\eta_{i \text{ init}} = 0.5 \text{ MPa s}$, and $\tau_{i \text{ init}} = 0.2 \text{ s}$. The identified parameters did not depend on these initial values. To evaluate the model efficiency, the determination coefficient, R^2 , was calculated for each experimental curve, leading to three coefficients for each muscle.

Since the constitutive laws employed are nonlinear, it is not valid to simply take the mean of the material parameters to obtain parameters describing an average fit. Instead, the parameters defining average fits were determined by the following procedure. Theoretical curves were generated for the same strain and time ranges using the constitutive equations (equation (8)), geometrical characteristics (mean section and length of the 10 specimens), and fitted parameters for each set (for each of the 10 parameter sets corresponding to each subject and for each velocity). These curves could then be used to define a single average curve for each velocity: three curves were obtained. Then, the mean parameters

were obtained by fitting the model on the three average engineering stress–engineering strain curves.

Results

Geometrical parameters were similar for all the muscles (Table 1). The mean initial length after the pre-load was 228 mm (standard deviation (SD): 28 mm), and the mean cross-sectional area was 153 mm^2 (SD: 75 mm^2). The engineering stress–engineering strain experimental curves presented the same shape for all the muscles (Figure 5). Inter- and intra-individual variabilities were observed, as well as an effect of velocity on the response. An increase in velocity led to an increase in the maximum stress measured. The average maximum stress was 0.46 MPa for 1 mm s^{-1} , 0.52 MPa for 10 mm s^{-1} , and 0.63 MPa for 100 mm s^{-1} (Figure 5). This result was confirmed by the statistical analysis. It showed that the maximum stress was sensitive to velocity changes (Figure 5). All the changes in velocity affected the maximum stress with an increase ranging from 13% to 37%. Therefore, the need for a nonlinear viscoelastic model was justified.

The strain and strain rates applied to the muscles changed because of the muscles' length. The maximum strain was between 2.9% and 4.3%, with a mean value of 3.6%. The average strain rate was 0.0045 s^{-1} (SD: 0.0005 s^{-1} , minimum: 0.0036 s^{-1} , maximum: 0.0054 s^{-1}) for 1 mm s^{-1} , 0.045 s^{-1} (SD: 0.005 s^{-1}) for 10 mm s^{-1} , and 0.45 s^{-1} (SD: 0.05 s^{-1}) for 100 mm s^{-1} .

The parameters of the nonlinear model at the first- and second-order are presented in Tables 2 and 3. They reflect the inter- and intra-individual variabilities of the results. The results also present high similarity. The results for the second-order model are almost exactly

the same as for the first-order model. The relaxation times are the same and the sum of viscosity parameters in the second-order model equals the viscosity parameter of the first-order model. Therefore, a first-order model is enough to characterize the muscles response. The non-linear viscoelastic models properly described the experimental curves. The mean determination coefficient R^2 was 0.98 (minimum: 0.95, maximum: 1.00) for all the muscles tested at 1 mm s^{-1} , it was 0.99 (minimum: 0.98, maximum: 1.00) at 10 mm s^{-1} , and it was 1.00 (minimum: 0.99, maximum: 1.00) at 100 mm s^{-1} . An example of the first-order model response is shown in Figure 6.

Discussion

The passive properties of postmortem human muscle tissue were studied using a simple nonlinear viscoelastic model. Tensile tests at various velocities were performed on 10 *extensor carpi ulnaris* muscles in vitro. The parameters of the model were identified using a nonlinear least-square method.

The tested muscles were obtained from aged males. These age group and gender features have an effect on the results presented in this article. Mechanical parameters of the model would probably have been different if muscles from a younger population or female subjects have been chosen. To be able to draw more general conclusions on the muscle mechanical properties, further experiments on a larger population are required.

The muscles were collected from human cadavers that were frozen at $-20 \text{ }^\circ\text{C}$ post rigor mortis and then slowly thawed at $4 \text{ }^\circ\text{C}$. Rigor mortis has an effect on muscle mechanical properties.^{17,38,40} Indeed, muscle stiffness increases significantly a few hours after death, when rigor mortis onsets.¹⁷ Nevertheless, as highlighted by Van Ee et al.,³⁸ the Young's modulus of muscles tested post rigor mortis was not statistically different from the Young's modulus of muscles tested before appearance of rigor mortis. However, the no-load region was larger for preconditioned muscles tested post rigor mortis compared to the ones tested before appearance of rigor mortis, leading to a less stiff response. Therefore, we can assume that the

Figure 6. Example of model fitting with experimental curves. The engineering stress–engineering strain curves obtained for one muscle at each velocity are compared with the results obtained with the nonlinear viscoelastic model.

mechanical properties of the muscles in this study were not affected by rigor mortis. However, these results were obtained for animal tissue and may differ from human tissue. The differences between the response of aged and fresh human tissue and between fresh human tissue and fresh animal tissue are unknown. Moreover, there is no evidence that viscoelastic properties are affected or not by rigor mortis. These points should be further investigated.

After collection, the muscles were preserved at -20°C until testing. Cryopreservation is known to alter the mechanical properties of soft tissues such as muscle. According to Ralis,⁴¹ ice crystals are formed within the tissue at temperatures between -15°C and -60°C , which damage the fibers of muscles. This was confirmed by Gottsauner-Wolf et al.²³ by histological analysis that highlighted the presence of lesions within the tissue. However, Van Ee et al.³⁸ showed that the post rigor freeze–thaw cycle was not found to affect the strain–stress response of muscle, and that if the mechanical properties were stabilized ahead of the test, measurements were repeatable, but would underestimate the response of a fresh muscle, or a live muscle. Consequently, experimental results are modified by this conservative method and must be interpreted with caution. To the best of the authors’ knowledge, the effects of freeze–thaw process on the viscoelastic properties of muscle tissue are unknown.

Regarding the strain, an elongation of 8 mm was applied to the whole structure, which represents a mean strain of 3.6% (SD: 0.5%). This value is in the range of what was obtained in the simulations, but it is low compared to strains observed in the literature. For instance, Best et al.³⁷ applied a strain of up to 12% on

rabbit muscles, and Bensamoun et al.⁴² applied 20% strain on rat muscles in tension. In Gras et al.,^{32,33} the strain applied to the human *sternocleidomastoideus* muscle reached 14%. However, the experimental protocols proposed in these studies differ from the one used with the *extensor carpi ulnaris* muscle, especially regarding the initial state. In Gras et al.,^{32,33} the preload applied to the muscle is 2 N, whereas it is 5 N in this study. This affects the tension in the muscle fibers and thus the strain that fibers can reach thereafter; muscle fibers were probably not only straighten but already stretched.²⁹ The *extensor carpi ulnaris* muscle is also a pinnate muscle, and therefore, the muscle fibers are smaller than in a fusiform muscle with parallel fibers; there is more connective tissue in the muscle and the tendons are inserted deeply in the muscle belly. Consequently, muscle stretching is more limited. Moreover, in preliminary tests, rupture of the muscle was observed when the applied displacement exceeded 10 mm. This explains the low strain which is relative, since the length of the muscle in situ was unknown.

The velocities applied to the muscles (1 , 10 , and 100 mm s^{-1}) correspond, respectively, to the following strain rates: 0.0045 , 0.045 , and 0.45 s^{-1} . The strain rates, as well as the strain applied to the muscles, were thus representative of what would have been experienced in a low severity impact. For general impact, higher strain and strain rates should be evaluated; however, the studied strain rates are still useful, for instance, for the development of pre-crash human body numerical models⁸ where loadings are lower than in crash situations and where muscles are modeled with 1D elements.

In the literature, Best et al.³⁷ used strain rates ranging from 0.01 to 2 s^{-1} to demonstrate the sensitivity to strain rate of rabbit muscles in tension. Taylor et al.⁴³ studied the viscoelastic response of rabbit muscle-tendon units. They were submitted to stretch ramps performed at 0.1 , 1 , 10 , and 100 mm s^{-1} ; yet the corresponding strain rates were not indicated. The tensile tests performed by Myers et al.^{25,26} on rabbit muscles were at strain rates of 1 , 10 , and 25 s^{-1} . Noonan et al.^{27,28} evaluated the effect of two velocities, 10 and 100 mm s^{-1} , that corresponded to 0.1 and 1 s^{-1} , on various parameters such as stiffness on rabbit muscles. In our study, even though the strain rates were lower than in Myers et al.,^{25,26} they were sufficiently different to highlight their effect on the muscle response, and thus to allow the identification of the viscoelastic parameters of the model.

Only the muscle initial length and cross-sectional area were used to assess the mechanical parameters of the model. They presented intra- and mostly inter-individual variabilities, especially the cross-sectional area. The entire geometry of the muscles has not been assessed in this study. If it would have been the case, subject-specific finite element models of each muscle could have been created to determine their mechanical properties with an inverse method. This could have

been helpful to identify the stress and strain distributions within the muscle; however, the goal of the study was only to obtain apparent mechanical properties of a human muscle that could be used for the definition of 1D muscles in numerical models. Therefore, only basic geometrical features were required to characterize the muscle response.³² In future work, these basic geometrical features could be easily derived from 3D geometry recorded, for instance, by a laser scanner.

The proposed nonlinear viscoelastic model is simple. Only four to six parameters are required to describe the response of the muscle in tension. The model is valid in this case for small strain values, but its ability to model muscle response at strain up to 14% has been previously showed.^{32,33} The hyper-elastic response described with an exponential law has been used to characterize the passive response of other human muscle in tension at a low strain rate.^{32,33} Regarding the viscoelastic behavior, a first- and second-order Maxwell model was chosen.^{13,21,33,43,44} In Gras et al.,³³ the second-order model gave better results than the first-order model; in this study, both models gave the same results. The second-order model allows a wider range of mechanical response.

The parameters identified with the model are specific to the *extensor carpi ulnaris* muscle of the selected age group and gender and for the specific experimental conditions including velocities and pre-load. The model's parameters were identified using three experimental curves. Another test may be useful to obtain a more precise estimate of the parameters. However, Taylor et al.⁴³ recommended no more than four tests on a same muscle, because of observed alteration of the muscle tissue thereafter. To ensure the measured response was not altered, we decided to test only three velocities.

The parameters are in the same order of magnitude as those reported in the literature; however, they are higher, in particular the Young's modulus E . The Young's modulus E in our study is in mean 6.8 MPa, whereas it was 2 MPa for a dog muscle in compression¹⁵ or a rabbit muscle in tension at 20% strain.²⁶ For a lower limb finite element model, Behr et al.¹ used a Young's modulus of 1 MPa in the tension direction and 5 MPa in the direction perpendicular to the tension direction. Gras et al.³² identified a Young's modulus of 0.1 MPa for the human *sternocleidomastoideus* muscle. Bosboom et al.¹³ used the Ogden's law to characterize the response of a rat muscle in compression; the equivalent Young's modulus was 0.05 MPa. An explanation for the high value of our Young's modulus is the fact that the *extensor carpi ulnaris* muscle is a pinnate muscle with a deep insertion of the tendons in the muscle belly. Hence, it presents a larger amount of connective tissue than a fusiform muscle such as the *sternocleidomastoideus* muscle, for instance. This modulus is an apparent modulus for the muscle structure. In addition, the initial state of the muscle affects the mechanical response as mentioned previously. Moreover, the calculation of the Young's modulus is based on the

calculated engineering stress. This stress depends on the cross-sectional area. This area was preferred over physiological cross-sectional area because muscle was elongated in its longitudinal direction, and not in the fiber direction. To improve the experimental protocol, medical imaging should be considered in order to obtain the physiological cross-sectional area.

The curvature parameter α was 31.6 in this study. For the *sternocleidomastoideus* muscle tested in tension, it was 24,^{32,33} and for a rat muscle in compression it was 21.¹³ Regarding the viscoelastic parameters η and τ , a comparison with the literature was not possible, because no comparable data were found.

Comparison with the literature is also limited, because very few experiments have been performed on human muscles.^{14,31–34} Moreover, as highlighted by Yamada,³⁴ high variability exists in the response of different human muscles. For instance, Gras et al.^{32,33} measured a stress of 0.01 MPa at 5% strain for the *sternocleidomastoideus* muscle and at a strain rate of 0.001 s^{-1} ; whereas in this work, at 3.6% strain and at the lowest strain rate (0.0045 s^{-1}) the average stress was 0.46 MPa for the *extensor carpi ulnaris* muscle. Even though the experimental protocol differs slightly from one experiment to the other and the physiological cross-sectional area is not considered to calculate the stress, there is a factor of 50 between the engineering stress measurements at the same strain for these two muscles. These values represent apparent properties of the muscle structure, including the muscle belly and connective tissue.

In conclusion, this work provides new knowledge of the passive mechanical behavior of human muscles in tension that could be useful in the field of impact biomechanics, as well as in biomechanics in general. It proposes a simple nonlinear viscoelastic model considering basic geometrical features to describe the passive response of muscles in tension. The results could be used in the definition of 1D muscles in human body numerical models developed to reproduce pre-crash events. However, it should be noted that these results are obtained for one specific muscle. Indeed, the results suggest the use of specific passive properties for different groups of muscles in human body models. Therefore, the approach proposed in this study could be reproduced to characterize other human muscles.

Acknowledgements

The authors would like to thank Yann Le Corvec for his technical support in the setting of the protocol. The authors are grateful to Dr Anthony Viste and Dr Frédéric Rongieras for muscle dissection.

Declaration of conflicting interests

None of the authors have any conflicts of interest to report.

Funding

This work was supported by the GDR 2610 “Biomécanique des chocs” (CNRS/INRETS/GIE PSA Renault).
