Abstract

The Romanesque abbey of Cluny was almost entirely destroyed after the French Revolution. As part of the *Cluny 2010* initiative (the commemoration of the 1100th anniversary of its foundation), the *Gunzo* project leads the research and promotion of the heritage of Cluny thanks to digital technologies and virtual reality. This interdisciplinary team is working on the creation of a digital model of the Cluny abbey according to the latest scientific research, including the archaeological excavations and the study of the documentary sources. Samples of polychromes and gildings were collected from selected lapidary fragments which are representative of different parts from the Romanesque Portal (jambs, lintel, tympanum and archivolts). Pigments and gildings were analysed using scanning electron microscopy (SEM), energy-dispersive X-ray spectrometry (EDS) and micro-Raman spectrometry. The physicochemical analyses point up the use of relatively expensive materials, such as gold leaves, lapis lazuli or cinnabar. Moreover, some blackish layers were identified as altered leaves of tin. The palette and abundance of metallic leaves should reflect the prestige of the abbots of Cluny.

Introduction

The year 2010 marks the 1100th anniversary of foundation of the greatest Romanesque abbey of Europe. Cluny – located in Burgundy, France – was synonymous with power. Put under the supervision of Rome, it was at the head of a vast network through all Europe. Its church, called *Major Ecclesia*, was the greatest of Christendom until the reconstruction of St-Peter's Basilica of Rome in the 15th century. It

had atypical attributes: 187 m in length, about 40 m in elevation under the dome of the great transept (the highest vault ever built), five naves, two transepts, 301 windows, five church towers. Unfortunately, it was almost entirely destroyed after the French Revolution (only eight percent is left undestroyed).

This research is related to a project of promotion of Cluny's heritage: *Cluny 2010, European abbey of knowledge*. *Gunzo*, an interdisciplinary team (engineers, art historians, archeologists, restorers among others), named after the abbey's legendary designer, leads the research thanks to digital technologies and virtual reality. The team is working on the creation of a new digital model of Cluny abbey based on the latest scientific research, including archaeological excavations, the study of documentary sources and the examination and analysis of decorations (paintings and stained glass windows).

Initially we were focused on the polychromy of the Romanesque entrance (1115-1120) of Cluny III. The immense portal (around 16.60 m high) represented a *Majestas domini*. The Christ enthroned in a glory is attended by angels, cherubim and the symbols of the four Evangelists on the tympanum, while, in the archivolts above, the Eternal Father, attended by the twenty-four elders and a circle of angelic beings, constitute the celestial Court of Heaven gathered to receive him. In 1810, the portal was blown up with gunpowder and only few mutilated fragments remain. In order to try to reconstitute it and its polychromes, we base our work on the previous results from Conant (1968) and Kleinschmidt (1970) who studied fragments of the 30s excavations and on new fragments excavated by G. Rollier at the end of the 80s. The remaining polychromes are sufficient to indicate the predominant colours of most of the decorative and iconographic elements.

Materials and Methods

About 40 samples of painting were collected from lapidary fragments discovered during archaeological excavations (K.-J. Conant in 1928-1950 and G. Rollier in 1988-89). The selected fragments are representative of different parts of the portal (jambs, lintel, tympanum, and archivolts). Their study provides data about the materials used for decoration (preparatory layers, pigments, metallic leaves) and helps us identify their alterations (significant in the case of a virtual restoration because of the colour changes it can create).

Polished cross-sections of stratigraphic sequences of these samples were prepared and examined under optical and scanning electron microscopes. Chemical analyses were per-

formed using energy dispersive X-ray spectrometry coupled with scanning electron microscopy (SEM) (JEOL JSM 6460LV – Oxford INCA 300). Structural analyses were carried out using micro-Raman spectrometry (Renishaw RM 2000), which allowed identifying pigments. The Raman spectra were collected using a laser excitation at 632.8 nm.

Results and Discussion

Stone and preparation

It seems that the two types of limestone used to build the Romanesque portal (Blanc *et al.*, 1990) have not kept the colours the same way. In the lower parts, in gray-beige oolitic limestone, more vulnerable to degradations, the coloured elements are often damaged. On the upper parts carved from a creamy-white limestone pisolithic, softer and more porous, the colours are better preserved.

A layer of lead white (Table 1) was generally used as preparation for the pictorial layers. Only the elements belonging to jambs have a yellow ochre preparation (Table 1), and St. Peter's, preserved in Rhode Island (USA), is

composed of lead white mixed with grains of vermilion [analyses carried out at the Conservation Department of the Fogg Art Museum (Cambridge, USA), in 1973].

Palette

The figures of the tympanum, lintel and archivolt stand out against a blue background. The chemical analyses show the presence of an aluminum and sodium silicate (Table 1). It's the lazurite, identified by Raman, and main component of the lapis lazuli. The latter is on a layer of carbon black mixed with lead white. The lapis lazuli is often put on a layer of carbon black in order to use less of the precious pigment.

Two samples, taken from the background of the lintel, presenting only the layer of lead white mixed with carbon black, were visually blue. Is it a deliberate optical effect, or is it due to the sampling?

Figure 1. Fragment of the first jamb (limestone, 40x35 cm) and coloured restitution. Reproduced with permission of S. Castandet and A. Mazuir, Arts et Métiers ParisTech, Cluny, France.

The red and green, juxtaposed, are widely used in the architectural framework and decorative carving (Figure 1). This combination of colours is very common in the Middle Ages.

Most of the red samples correspond to vermilion applied on a layer of red lead (Table 1); these pigments are sometimes mixed. The red ochre is seldom used, at least in the context of this study (remaining and studied fragments); on the other hand, this pigment is more abundant on the occidental Gothic portal.

The green layers are made of a copper-based matrix containing lead-tin yellow (Table 1).

The copper-based matrix showed a low Raman scattering and no bands corresponding to malachite or verdigris, suggesting the use of a copper resinate. The use of lead-tin yellow raises the problem of the layers' age. Not attested before 1300 (Kühn, 1963), moreover lead-tin yellow appears in the polychromes of the Jean de Bourbon chapel (small transept), which dates back to the 15th century. Is it a non-original layer of the Gothic period? In this case, we will not be able to reconstitute the Romanesque colours of the portal but the colours of a certain period. A sample (Bdx 14301) shows a green

layer covered by three coloured layers (Figure 2); the latter consists of lead-tin yellow, which tends to support the hypothesis of a Gothic repaint. The green layer, probably original, consists of a green copper pigment (presence of copper oxide) that the spectrometry Raman had not permitted to identify.

The flesh tones are a mixture of lead white and vermilion (Table 1) as illustrate the almost entirely polychrome sleeping soldier's head (presumed scene of the Holy Women at the Tomb on the left of the lintel) (Figure 3) and the coloured remains of Saint Peter's face, formerly located in the upper part of the Romanesque facade.

A black border, more or less pronounced, highlights eyes, beards and mustaches of faces (Figure 3). The obtained Raman spectrum shows the two main peaks at 1300 cm⁻¹ and 1550 cm⁻¹ characteristics of carbon black.

Gildings

The brilliance of colours was reinforced by the abundant use of gilding (Figure 4), located around the Christ (halo, mandorla and clouds of angels), and on the lintel (haloes of apostles) or on the archivolts (haloes and hairs of angels, rosettes). The portal includes two kinds of metallic decoration: gold and tin leaves (Table 1). The chemical analyses highlight certain blackish layers corresponding to altered leaves of tin (Figure 5). We cannot say if the tin leaves were employed in imitation of silver or gold. In the case of gold imitation, the Benedictine monk Theophilus gives a recipe of coloured varnish in order to *gild* tin (Théophile, 1996). We think tin was used as gold substitute because the fragments of the mandorla are *gilded* either gold or tin and the Christ's halo is covered with tin while all other halos are covered with gold leaves.

Repaints

Different repaints have been highlighted such as the vermilion on the gilded rosettes of the archivolts, the azurite – less costly – covering the lapis lazuli or the green containing the lead-tin yellow. Several samples have two pictorial medieval layers, one, probably Romanesque, subsisting only on some fragments, and the other, Gothic, with the lead-tin yellow. The Romanesque portal was built in 1115-20, followed by a long period of construction of the narthex. At the time of completion of the Gothic facade in the middle of the 13th century, a restoration of the Romanesque portal probably occurred to dust it and revive its colours. This is reminiscent at the cathedral of Bourges, where a first portal coloured around 1225, was restored thirty years later, at the completion of the portals of the west facade. Subsequently, the brilliant polychromes of the portal of Cluny were covered, probably at two different times, by two relatively thick layers of white lime wash (Table 1).

Figure 2. Stratigraphic section of a sample from a fragment of angel wing belonging to the archivolts (Bdx 14301). The green of the first coloured layer consists of a copper-based pigment, while the yellow-green of the upper layer is a repaint of lead-tin yellow (magnification x200). Reproduced with permission of S. Castandet, Centre de Recherche en Physique appliquée à l'Archéologie, Bordeaux, France.

Figure 4. First try of coloured restitution (with permission of Enodo, Nice and Arts et Métiers ParisTech, Cluny).

Figure 5. Sample of altered gilding belonging to the rosettes of the jambs (Bdx 13328). Pictures in natural light of this sample (a) and its cross-section and scanning electron microscopy picture of the cross-section (b). Reproduced with permission of S. Castandet, Centre de Recherche en Physique appliquée à l'Archéologie, Bordeaux, France.

Conclusions

Physicochemical analyses reveal the use of relatively expensive materials, such as gold leaves, lapis lazuli or vermillion and certain blackish layers were identified as altered leaves of tin. The knowledge of the original material is a prerequisite in a virtual restitution.

The analytical results allow a first attempt of coloured restitution of the Great Portal of Cluny (Figure 4). The repaints such as azurite and the lead tin yellow indicate at least two polychrome phases.

The history, the restoration and the analytical results will be gathered in a database associated with the 3D virtual restitution.
