# Micromechanics-Based Damage Analysis of Fracture in Ti5553 Alloy with Application to Bolted Sectors

Mohamed Ben Bettaieb, Thibaut Van Hoof, Hans Minnebo, Thomas Pardoën, Philippe Dufour, Pascal J. Jacques, and Anne Marie Habraken

A physics-based, uncoupled damage model is calibrated using cylindrical notched round tensile specimens made of Ti5553 and Ti-6Al-4V alloys. The fracture strain of Ti5553 is lower than for Ti-6Al-4V in the full range of stress triaxiality. This lower ductility originates from a higher volume fraction of damage sites. By proper heat treatment, the fracture strain of Ti5553 increases by almost a factor of two, as a result of a larger damage nucleation stress. This result proves the potential for further optimization of the damage resistance of the Ti5553 alloy. The damage model is combined with an elastoviscoplastic law in order to predict failure in a wide range of loading conditions. In particular, a specific application involving bolted sectors is addressed in order to determine the potential of replacing the Ti-6Al-4V by the Ti5553 alloy.

**Keywords** aircraft engine, complex loading, ductile fracture, FE validation, notched samples, stress triaxiality, Thomason model

## 1. Introduction

Titanium (Ti) alloys are heavily used in aeronautic structures owing to their exceptional strength/density compromise. In particular, titanium constitutes an enabling material for aircraft engine components working at intermediate temperatures (200-400 °C). Engine elements undergo severe mechanical loadings, especially under accidental conditions such as during a fan blade out event. The design of structural parts must account for different possible failure scenarios. For almost 50 years, Ti-6Al-4V is the most common Ti alloy in aerospace components for almost 50 years. It accounts for more than 50% of the Ti production worldwide. In the temperature range of interest (200-400 °C), Ti-6Al-4V is known to fracture as a result of the growth and coalescence of voids which nucleate at the interface between the  $\alpha$  and  $\beta$  phases. A recent trend in the aeronautics industry is to monitor the progress in the development of new generations of Ti alloys, such as the Ti5553 (Ref 1, 2), in order to detect potential candidates that could advantageously replace

the Ti-6Al-4V alloy owing to enhanced mechanical performances and/or lower cost.

There are two objectives in the present work. First, an uncoupled ductile fracture model describing the nucleation, growth, and coalescence of voids is proposed, calibrated and validated for both the Ti-6Al-4V and Ti5553 alloys. The selection of the model was guided by the need to find a proper balance between simplicity and accuracy while maintaining a close link with the physics of ductile failure. Second, the potential of the Ti5553 alloy is evaluated in the case of a specific application of bolted sectors of an aircraft engine where the question of ductile fracture is one of the key limiting issues. This application illustrates how the damage model developed in this study can be transferred to real applications.

Two different generic approaches exist to model ductile damage and fracture: the coupled or the uncoupled approach. In the coupled approach, the damage accumulation interacts with the stress and strain evolution owing to a dilatant plasticity formulation. Constitutive models including damage have been formulated based on continuum thermodynamics (e.g., Ref 3, 4) or on micromechanics-based description of voided materials (e.g., Ref 5-10). In the uncoupled approach, the stress and strain fields are assumed to be unaffected by damage. Thus, the damage evolution is calculated using elastoplastic or elastoviscoplastic constitutive equations (Ref 11), as envisioned in the pioneering works of McClintock (Ref 12) and Rice and Tracey (Ref 13), see also recent applications (see Ref 14, 15). The damage evolution can then be computed as a part of the post-processing analysis. In the present work, the uncoupled approach has been preferred in order to simplify the structural analysis. The choice will be justified also by the fact that damage nucleates relatively late in the deformation process and that the porosity remains quite small until fracture.

Following the pioneering works by Pineau and co-workers (Ref 16), the analysis of damage accumulation and the calibration of the model parameters rely on tensile tests performed on cylindrical notched round specimens, see also (Ref 7, 14, 17-19). A wide range of stress triaxiality, which is the key parameter controlling the rate of damage in plastically deforming materials, can be covered by changing the radius of

the notch. The elastoviscoplastic material model generated on the basis of the experimental results described in Ref 20 is used to simulate the mechanical tests and to compare the mechanical response of the Ti5553 alloy with the response of the Ti-6Al-4V alloy for a specific structural component.

The outline of the paper is the following:

- In section 2, the chemical composition and heat treatments of the different microstructures are presented;
- In section 3, the elastoviscoplastic model and parameters calibration described in Ref 20 are summarized.
- In section 4, the damage model is presented and the parameters are calibrated on the basis of tensile tests performed on smooth and notched specimens.
- In section 5, the difference between the Ti5553 and Ti-6Al-4V alloys is addressed through the analysis of the mechanical response (elastoviscoplastic behavior and fracture modeling) of a component made of bolted sectors of an aircraft engine under various loading conditions.
- Section 6 summarizes the main conclusions of the study.

## 1.1 Units

The international system of units (SI) is used in this paper:

- The stress is expressed in MPa.
- The strain rate is expressed in  $s^{-1}$ .

## 2. Materials

As for all metallic alloys, the mechanical properties of Ti alloys are very sensitive to the initial microstructure, thermo-mechanical loading history, and chemical composition (Ref 21-24). From a microstructural point of view, the Ti-6Al-4V and Ti5553 alloys are significantly different in terms of volume fraction and morphology of the primary  $\alpha$  phase and transformed  $\beta$  phase. A detailed comparison between the microstructures of the two alloys is given in Ref 2.

### 2.1 Alloy Ti-6Al-4V

**2.1.1 As-Received Ti-6Al-4V.** The Ti-6Al-4V specimens are directly machined, in the  $0^\circ$  direction, from a forged part provided by the company Techspace Aero (Fig. 1a).

The Ti-6Al-4V alloy investigated in this work is made of equiaxed primary  $\alpha$  grains and secondary  $\alpha$  lamellae dispersed in the  $\beta$  matrix (Fig. 1b). The volume fraction of  $\alpha$  phase is between 80 and 90%. The transus temperature is about  $995^\circ\text{C}$  (Ref 2, 21). After forging in several steps in the  $\alpha + \beta$  domain, the final heat treatment consists in an annealing performed at  $750^\circ\text{C}$  (1 h) followed by air cooling.

**2.1.2 Chemical Composition.** The chemical composition from the top and bottom regions of the initial ingot (used to machine the forged component of Fig. 1a) is reported in Table 1.

The molybdenum equivalent in terms of chemical composition is defined as follows (Ref 25):

$$\text{wt.\%Mo.Eq.} = 1.0(\text{wt.\%Mo}) + 0.66(\text{wt.\%V}) + 0.33(\text{wt.\%N}) + 3(\text{wt.\%Fe}) + 3(\text{wt.\%Cr}). \quad (\text{Eq 1})$$

Using the above table and formula, the Mo-equivalent was estimated as equal to 3.48.

### 2.2 Ti5553 Alloy

Ti5553 involves a large amount of  $\beta$  stabilizer elements such as Mo, V, Fe, and Cr (see chemical composition in Table 2). The transus temperature is about  $860^\circ\text{C}$  (Ref 22). This alloy is

**Fig. 2** Ti5553 material: (a) forged pancake, (b) final heat treatment cycle of the two microstructures, (c) scanning electron microscopy micrographs of microstructure Ti5553-1 (aging at 610 °C), and (d) scanning electron microscopy micrographs of microstructure Ti5553-3 (aging at 670 °C)

highly sensitive to minute variations in the heat and thermo-mechanical treatments. This sensitivity has a significant impact on the microstructure as demonstrated hereafter.

The material of the study has been provided by the company Techspace Aero in the form of forged pancakes (Fig. 2a). The forging of the pancakes was performed at 815 °C using a 2500 tons forging press. The final thickness of

the pancakes is equal to 47 mm. Based on the chemical composition (Table 2) and Eq 7, the Mo equivalent was estimated as equal to 18.18. The specimens used to characterize the elastoviscoplastic behavior are machined in the 0° direction.

The chemical composition from the top and bottom regions of the ingot is reported in Table 2.

The final heat treatment used to generate the two Ti5553 microstructures is the following (see Fig. 2b):

- Ti5553-1: heated from room temperature up to 830 °C + hold at 830 °C during 2 h + air cooling + aging at 610 °C during 8 h + air cooling;
- Ti5553-3: heated from room temperature up to 830 °C + hold at 830 °C during 2 h + air cooling + aging at 670 °C during 8 h + air cooling.

The resulting microstructures are made of equiaxed primary  $\alpha$  grains and secondary  $\alpha$  needles embedded in the  $\beta$  matrix. These two microstructures are thus bi-modal; the primary  $\alpha$  phase involves a nodular morphology and the secondary  $\alpha$  is lamellar. The volume fraction of  $\alpha$  phase is about 20%.

The first aging at 830 °C (Fig. 2b) is responsible for the nucleation of the  $\alpha$  nodules. This aging is the same for both microstructures, explaining why there is no difference between the morphology and the size of the nodular  $\alpha$  phase. The only difference between the two microstructures is related to the aging temperature. This temperature was responsible for the formation of the secondary  $\alpha$  phase, which contains needles like particle shape or very small plates. The microstructure of Ti5553-1

shown in Fig. 2(c), is slightly finer compared to the Ti5553-3 microstructure shown in Fig. 2(d), due to a lower aging temperature (610 °C). Note that the presence of the secondary  $\alpha$  phase is an important source of hardening in the alloy.

### 3. Elastoviscoplastic Model

In Ref 20, the elastoviscoplastic behavior of Ti5553 has been characterized and compared to the classical Ti-6Al-4V. The true stress-strain curves were determined from uniaxial tensile tests performed under different strain rates at room temperature and at 150 °C. The Young's modulus of Ti-6Al-4V and Ti5553 are given in Table 3. The Poisson ratio is assumed to be independent of strain rate and temperature, and found to be close to  $0.33 \pm 0.03$  for the different alloys and microstructures.

On the basis of these tensile tests, the parameters of the Norton-Hoff model (Ref 26, 27) were calibrated. The Norton-Hoff law, which is frequently used for Ti alloys (Ref 28, 29), writes:

$$\sigma_{eq} = \exp(-P_1 \epsilon_{eq}) \sqrt{3} P_2 (\sqrt{3} \dot{\epsilon}_{eq})^{P_3} \bar{\epsilon}_{eq}^{P_4}, \quad (\text{Eq 2})$$

where  $\sigma_{eq}$ ,  $\epsilon_{eq}$ , and  $\dot{\epsilon}_{eq}$  are the Von Mises equivalent stress, equivalent strain, and equivalent strain rate, respectively:

$$\sigma_{eq} = \sqrt{\frac{3}{2}} \hat{\sigma}_{ij} \hat{\sigma}_{ij}; \quad \dot{\epsilon}_{eq} = \sqrt{\frac{2}{3}} \hat{\epsilon}_{ij} \hat{\epsilon}_{ij}; \quad \epsilon_{eq} = \int_0^t \bar{\epsilon} dt; \quad (\text{Eq 3})$$

where  $\hat{\sigma}_{ij}$  are the deviatoric components of the stress tensor;  $\hat{\epsilon}_{ij}$  are the deviatoric components of the strain rate tensor; and

Fig. 3 Geometry of the smooth and notched specimens (dimensions in mm)

Fig. 4 Measurement of the cross-section area after fracture: (a) experimental setup and (b) optical micrograph of a reconstituted specimen

$P_1, P_2, P_3,$  and  $P_4$  are a softening parameter, a scaling factor, the strain rate sensitivity exponent, and the hardening exponent, respectively.

The  $J_2$  viscoplastic theory is based on the following set of equations (Ref 28):

$$\hat{\epsilon}_{ij} = \frac{3\dot{\epsilon}_{eq}}{2\sigma_{eq}} \hat{\sigma}_{ij}. \quad (\text{Eq 4})$$

Hence, the relationship between the deviatoric stress,  $\hat{\sigma}_{ij}$ , and the deviatoric strain rate,  $\hat{\epsilon}_{ij}$ , tensors writes for a Norton-Hoff hardening law:

$$\hat{\sigma}_{ij} = 2P_2(\sqrt{3}\dot{\epsilon}_{eq})^{P_3-1}(\epsilon_{eq})^{P_4} \exp(-P_1\epsilon_{eq})\hat{\epsilon}_{ij}. \quad (\text{Eq 5})$$

The viscoplastic parameters  $P_1, P_2, P_3,$  and  $P_4$  determined from the calibration procedure at RT and 150 °C are given in Table 4.

As demonstrated in Tables 5 and 6, the strength of Ti5553 is 20-40% higher than the strength of Ti-6Al-4V. Ti5553 consti-

tutes thus a promising candidate for advanced structural applications.

The elastic and plastic initial anisotropy of both alloys has been investigated by combining compression on cylinders with elliptical sections, uniaxial tensile tests in different material directions, plane strain, and shear tests, see Ref 20. The conclusion is that the initial anisotropy of the different alloys is weak which justifies modeling the mechanical behavior with an isotropic version of the Norton-Hoff model.

## 4. Damage Analysis Using Cylindrical Notched Round Specimens

### 4.1 Description of the Mechanical Tests

Tensile tests were performed at room temperature (RT) and at 150 °C on cylindrical notched round bars with three different

**Fig. 5** Effect of strain rate and of temperature on the fracture strain under uniaxial tension conditions: (a) Ti5553-1, (b) Ti5553-3, and (c) Ti-6Al-4V

**Fig. 6** Overall experimental axial stress as a function of the axial strain for the smooth and notched round specimens tested at room temperature (3 or 2 tests for each conditions): (a) Ti5553-1, (b) Ti5553-3, and (c) Ti-6Al-4V

notch root initial radii  $R_0 = 1, 2,$  and  $4$  mm (see Fig. 3). The initial diameter of the minimum cross-section was kept constant, equal to  $6$  mm for all test specimens. The different notches induce different levels of stress triaxiality (the stress triaxiality  $T$  is defined as the ratio between the hydrostatic stress  $\sigma_h$  over the von Mises equivalent stress  $\sigma_{eq}$ , i.e.  $T = \sigma_h/\sigma_{eq}$ ). Three duplicate tests were conducted for each condition of temperature, notch radius, alloy, and heat treatment. The applied load, crosshead displacement, and reduction of diameter of the minimum cross-section were continuously recorded during the test.

The ductility of the material, defined by the true average fracture strain  $\varepsilon_f$ , is calculated as:

$$\varepsilon_f = \ln\left(\frac{S_0}{S_f}\right), \quad (\text{Eq 6})$$

where  $S_0$  and  $S_f$  are the initial and final cross-section areas, respectively. The initial value  $S_0$  was accurately measured prior to testing.

The minimum cross-section area after fracture  $S_f$  is determined using optical microscopy micrographs, after reconstitution of the broken specimen, see Fig. 4(a). The cross-section is assumed to be elliptical. The minor and major diameters are identified visually, and the corresponding coordinates,  $X_1$  and  $X_2$  (see Fig. 4b), are measured. The difference  $X_2 - X_1$  provides

the magnitude of the diameter. The cross-section is computed by means of the equation of an ellipse.

Note that this approach assumes an homogenous strain distribution within the minimum cross-section. This assumption is not very accurate. Indeed, the true local fracture strain which corresponds to the initiation of a crack (usually in the center of the specimen) is slightly smaller than the average value  $\epsilon_f$  (see, e.g., Ref 30). Nevertheless,  $\epsilon_f$  provides a relevant index to rank the ductility of materials (see Fig. 5) and a global calibration parameter for damage modeling.

## 4.2 Experimental Results

**4.2.1 Effect of the Strain Rate and Temperature on the Fracture Strain.** Figure 5 shows the variation of the fracture strain corresponding to uniaxial tension conditions (i.e., no notch) as a function of strain rate for the three different materials and the two test temperatures. In Ref 20, it was shown that the strength of the Ti alloys varies with strain rate. Nevertheless, the strain rate effect on  $\epsilon_f$  is rather small except for the tests at room temperature on Ti5553-1. Note that several studies have addressed the effect of the strain rate on ductility (Ref 19, 31-33). The fracture strain sometimes decreases with increasing strain rate due to an increase of the strength which, in turn, induces earlier void nucleation, while it sometimes increases with increasing strain rate due to local heating. Figure 5 shows that the ductility of both Ti5553 and Ti-6Al-4V increases with increasing temperature. This result is consistent with other experimental studies on Ti alloys (Ref 34-36). We attribute the limited increase of fracture strain with strain rate to

Fig. 7 Variation of the fracture strain as a function of the stress triaxiality at RT

the increase of temperature at higher strain rates promoted by the low thermal conductivity of Ti. Note that, finally, the dispersion on  $\epsilon_f$  at the same strain rate is sometimes quite large. This dispersion is presumably due to mesoscale microstructure heterogeneities such as macrozones. Further investigations are required in order to better understand and rationalize the origin of this dispersion.

**4.2.2 Effect of Stress Triaxiality on Fracture.** The RT overall experimental axial stress versus axial strain for smooth and notched round specimens tests are compared in Fig. 6 (three curves for each radius corresponding to the three repetitions). The average stress is calculated by dividing the experimental force by the current minimum cross-section area. The curves corresponding to uniaxial tension are interrupted at maximum load. The corresponding fracture points are indicated in the figures as well. The stress at fracture is calculated as the force just before fracture divided by the measured area at fracture, and the corresponding strain is calculated using Eq 6. Note that the apparent elastic modulus (the slope of the stress-strain curve) increases with increasing stress triaxiality which can be easily explained by application of Hooke's law in the presence of transverse stress.

Many experimental investigations have demonstrated that the fracture strain (see Eq 6) strongly depends on stress triaxiality (Ref 37-41). Two methodologies are typically used to evaluate the stress triaxiality: the first one is analytical and is based on the Bridgman analysis (Ref 42) and the second is numerical and based on FE simulations. The latter is more accurate and more realistic than the Bridgman formula, and it is thus used here for the notched specimens. The fracture strain  $\epsilon_f$  is plotted in Fig. 7 (see also Table 7) as a function of the average stress triaxiality (computed over the minimum section just before rupture) numerically predicted by using Lagamine FE code (Ref 43).

The connection between fracture strain  $\epsilon_f$  and stress triaxiality  $T$  for the different specimen geometries is given in Table 7.

As expected, the ductility heavily depends on stress triaxiality, see also, e.g., Ref 13, 43.

The fracture strain of Ti-6Al-4V is significantly higher than for both Ti5553 microstructures. The lower ductility of Ti5553 can be empirically correlated to the Mo-equivalent, as explained in Ref 20, 44. The alloy Ti5553 involves a Mo-equivalent value almost five times larger than in the Ti-6Al-4V alloy. Ti5553-3 is almost two times more ductile than Ti5553-1. The model developed in next section provides additional insights about the origins of the differences in fracture strain through a direct link with the underlying damage mechanisms.

## 4.3 Damage Model

Several studies in the literature (Ref 45-47) show that the Ti alloys often fail by a ductile fracture mechanism. A damage

**Fig. 8** Comparison between model predictions and experimental results in terms of the variation of fracture strain with average stress triaxiality: (a) Ti5553-1 at RT, (b) Ti5553-3 at RT, and (c) Ti-6Al-4V at RT. The variation of  $\epsilon_{nuc}$  is also provided

**Table 8** Parameters of the damage model calibrated for the different alloys and microstructures

	$\chi_0$	$\sigma_{nuc}$ , MPa	$k$
Ti-6Al-4V	0.44	1691	2.21
Ti5553-1	0.78	1974	4.26
Ti5553-3	0.78	2270	4.57

model must ideally integrate all the relevant physical phenomena in order to allow relating the microstructure to the damage and fracture resistance. More precisely, in most metals, ductile fracture proceeds by the nucleation of voids through decohesion or fracture of second phase particles, followed by the growth of the voids, involving also an evolution of the shape,

up to a point where plastic deformation starts localizing in the ligament between the voids. This last step is the onset of the void coalescence mechanism. After the onset of coalescence, coalescence by impingement of the voids follows quickly leading to the generation of a microcrack that can then propagate in the entire material. One can thus consider that the onset of coalescence constitutes the physical failure condition, being a good indicator of the point at which a material element loses its load carrying capacity (see Ref 30, 48) for more detailed discussions). An attempt is made in the present study to use a micromechanics based damage model based on the Beremin's nucleation condition (Ref 49), on the Rice and Tracey model (Ref 13) for the dilatational part of the growth of the voids and on the Thomason coalescence criterion (Ref 50). These models are supplemented by evolution laws for the void aspect ratio and for the void spacing ratio as proposed in Ref 51 for initially penny shaped cavities.

Beremin's void nucleation criterion (Ref 49) writes

$$\sigma_{\text{nuc}} = \sigma_{\text{princ}}^{\text{max}} + k(\sigma_{\text{eq}} - \sigma_0), \quad (\text{Eq 7})$$

where  $\sigma_{\text{princ}}^{\text{max}}$  is the maximum principal stress;  $k$  is a function of the particle shape and of the loading direction;  $\sigma_{\text{eq}}$  is the equivalent Von Mises stress; and  $\sigma_0$  is the initial yield stress.

The Thomason coalescence condition is expressed by

$$\left(\frac{\sigma_{\text{princ}}^{\text{max}}}{\sigma_{\text{eq}}}\right) \frac{1}{(1 - \chi^2)} = \alpha \left(\frac{1 - \chi}{\chi W}\right)^2 + 1.24 \sqrt{\frac{1}{\chi}}, \quad (\text{Eq 8})$$

where  $W$  is the current void aspect ratio estimated using (see Ref 51):

$$W = \lambda_0 \frac{\exp(\varepsilon - \varepsilon_{\text{nuc}}) - 1}{\exp((\varepsilon - \varepsilon_{\text{nuc}})/2)} \quad (\text{Eq 9})$$

and  $\chi$  is the current void spacing (see Ref 51)

$$\chi = \chi_0 \frac{\exp(\varepsilon/2)((C - 1) \exp[C(\varepsilon - \varepsilon_{\text{nuc}})] + 1)}{C} \quad (\text{Eq 10})$$

with

$$C = 0.427 \exp\left(\frac{3}{2}T\right) \quad (\text{Eq 11})$$

and where  $\varepsilon$  is the maximum principal strain;  $\varepsilon_{\text{nuc}}$  is the maximum principal strain required to nucleate a cavity (threshold value). This strain is determined using Beremin's condition as explained later;  $\lambda_0$  is a factor describing the degree of anisotropy in the void distribution;  $\chi_0$  is the initial relative void spacing;  $C$  is a variable dependent on the stress triaxiality  $T$  (see Eq 11). The expression of  $C$  has been assessed by several authors (e.g., Ref 52) and gives satisfactory predictions as long as the void volume fraction is sufficiently small, which is the basic underlying assumption of the Rice and Tracey analysis dealing with isolated void (Ref 13). The factor '0.427' appearing in the expression of  $C$ , instead of '0.283' as initially proposed by Rice and Tracey, has been re-computed by Huang (Ref 53); see also a recent work based on tomography measurements for a re-assessment of this model in the case of Ti-6Al-4V (Ref 54).  $\alpha$  is a fitting parameter related to the strain hardening exponent. The parameter has been fitted as a function of the average value of the strain hardening exponent  $n$ :  $\alpha(n) = 0.1 + 0.22n + 4.8n^2$  (Ref 55), see Ref 56 for alternative approaches.

In the case of axisymmetric loading and constant stress triaxiality, the following equation applies:

$$\frac{\sigma_{\text{princ}}^{\text{max}}}{\sigma_{\text{eq}}} = T + \frac{2}{3}, \quad (\text{Eq 12})$$

leading to the simplified expression for the coalescence criterion:

$$\frac{T + (2/3)}{(1 - \chi^2)} = \alpha \left(\frac{1 - \chi}{\chi W}\right)^2 + 1.24 \sqrt{\frac{1}{\chi}}. \quad (\text{Eq 13})$$

For a given stress triaxiality  $T$ , coalescence occurs for a strain  $\varepsilon = \varepsilon_f$  such that Eq 13 is fulfilled. We thus assume that fracture corresponds to the onset of coalescence (see Ref 57 for a discussion about the validity of this assumption).

The parameter  $\varepsilon_{\text{nuc}}$  (which appears in the expression of  $\chi$  and  $W$ ) is determined via the axisymmetric loading assumption

under constant stress triaxiality in two steps. First, Eq 7 and 12 are combined as

$$\sigma_{\text{eq}}(\varepsilon_{\text{nuc}}) = \frac{\sigma_{\text{nuc}} + k\sigma_0}{k + T + 2/3}. \quad (\text{Eq 14})$$

Then the function  $\varepsilon_{\text{nuc}}(\sigma_{\text{e}})$  is determined on the basis of a Newton-Raphson procedure based on the Norton-Hoff law  $\sigma(\varepsilon)$  developed in section 3. In this fitting procedure, the strain rate is assumed to be equal to  $0.001 \text{ s}^{-1}$ . This value corresponds to the mean strain rate in the center of the notched specimens as determined by the FE simulations.

#### 4.4 Calibration of the Damage Law

The adopted damage model is defined by four parameters ( $k$ ,  $\lambda_0$ ,  $\chi_0$ ,  $\sigma_{\text{nuc}}$ ) in addition to the hardening law, and is dependent on two variables: the strain  $\varepsilon$  in the tensile direction (elastic strains are neglected) and the stress triaxiality  $T$ . In order to simplify the calibration procedure, the parameter  $\lambda_0$  has been fixed equal to one which implies an initial isotropic distribution of voids. The other parameters ( $k$ ,  $\chi_0$ ,  $\sigma_{\text{nuc}}$ ) are calibrated from the experimental results  $\varepsilon_f = f(T)$  of Fig. 7. The calibration procedure is based on the *l-bfgs-b* optimization algorithm standing for "limited-memory Broyden-Fletcher-Goldfarb-Shanno algorithm." For more details about this algorithm, see (Ref 58-61). The calibration procedure turned out to have several shortcomings which are ultimately related to the complexity of the model:

- The stress triaxiality is assumed to be constant during the test (which is not exactly true in the practice).
- The solution is often not unique, due to the large number of parameters to be calibrated.

**Fig. 9** (a) Geometric description of the studied system, (b) mesh, boundary conditions and loadings

**Fig. 10** True stress-true strain response of Inconel 718 alloy at different strain rates (expressed in  $s^{-1}$ ) and temperatures: (a) at RT and (b) at 150 °C

**Table 9** Calibrated mechanical parameters of Inconel 718 alloy: elasticity and parameters of the Norton-Hoff viscoplastic law

	$E$ , GPa	$\nu$	$P_1$	$P_2$ , MPa	$P_3$	$P_4$
RT	212	0.35	$5.27 \times 10^{-5}$	1187.97	$5.868 \times 10^{-7}$	0.1112
150 °C	212	0.35	0.002	1125.73	$1.85 \times 10^{-4}$	0.1112

- The damage model is a micromechanics based model. However, the parameters are calibrated on the basis of macroscopic tests by inverse modeling.
- Perfect solutions in a calibration procedure involving only  $R_0 = 2$  and  $R_0 = 4$  test conditions sometimes lead to poor predictions for the other tests (smooth samples and  $R_0 = 1$  samples).

The results of the calibration are presented in Fig. 8 along with the experimental measurements, and the corresponding data are summarized in Table 8.

The curves present the best fit of all experimental data in the least square sense by the damage model.

If we assume that the premises of the model are correct, the results presented in Fig. 8 indicate that fracture is dominated by the void nucleation stage in Ti5553-3 at all stress triaxiality (i.e., fracture rapidly follows void nucleation). Ti5553-3 and Ti-6Al-4V involves a more extended void growth stage, especially at high stress triaxiality. The value of  $\chi_0$  can be qualitatively related to the relative spacing of the nearest neighbors  $\alpha$  nodules (see Fig. 2c and d). Note also that in Ref 54, 62, in situ 3D tomography tests on smooth bars of Ti-6Al-4V show the first occurrences of void nucleation events at a strain of  $\sim 0.3$  in excellent agreement with the inverse calibration performed here. The origin of the better resistance to void nucleation in the microstructure Ti5553-3 is an important finding. This is an example of microstructure engineering where failure has been postponed while not compromising on strength. Further investigation is needed to elucidate why the

**Table 10** Effect of the temperature on the yield stress  $\sigma_{p0.2}$  and the ultimate stress  $\sigma_u$  of Inconel 718

	RT	150 °C
$\sigma_{p0.2}$ (MPa)	1240	1140
$\sigma_u$ (MPa)	1680	1584

**Fig. 11** Effect of strain rate and of temperature on fracture strain in Inconel 718

coarser Ti5553-3 microstructure (compared to the Ti5553-1) is beneficial. It might have to do with lower local stress concentration promoted by a larger length scale.

## 5. Application to a Bolted Sector Component

The viscoplastic model based on the Norton-Hoff law calibrated for each material over a wide range of strains and strain rates is combined to the damage model presented in section 4 to analyze the mechanical behavior of an aircraft engine stator manufactured by the company Techspace Aero. The aim of the simulations is to compare the potential of the Ti5553 alloy compared to the Ti-6Al-4V in an industrial context.

The component of interest is composed of two sectors of an aircraft engine stator (downstream and upstream) attached together by bolted flanges as depicted in Fig. 9(a). The bolted flanges are made of Inconel 718, and the sectors are made of Ti-6Al-4V in the current design. There are three main objectives in this application:

- to validate the Norton-Hoff model previously calibrated on the Ti-6Al-4V alloy by comparing the results of the experimental tests performed on a real aircraft engine stator (in the M&S laboratory in ULg) with the numerical predictions, see section 5.3.
- to use the uncoupled damage model presented and calibrated in section 4 to predict the damage limit of the aircraft engine stators, see section 5.4.

### 5.1 Mechanical Behavior of Inconel 718 Alloy

The bolts are made of an Inconel 718 alloy. The mechanical properties of this material have been obtained using uniaxial tensile tests at four strain rates ( $5 \times 10^{-5}$ ,  $2 \times 10^{-4}$ ,  $4 \times 10^{-3}$ , and  $10^{-2} \text{ s}^{-1}$ ) and at two temperatures (RT and  $150 \text{ }^\circ\text{C}$ ). Three tests were performed for each strain rate and each temperature using the same geometry and dimensions as Fig. 3. Figure 10 shows that the dispersion in the stress-strain response of this alloy is small and that there is no strain rate effect. The elasticity constants and the Norton-Hoff parameters have been calibrated (see Table 9) using the same calibration procedure as applied in Ref 20 to the Ti alloys. The strength of the Inconel 718 alloy is not as sensitive to temperature as the Ti alloys.

Table 10 gathers the yield stress  $\sigma_{p0.2}$  (experimentally measured at 0.2% of plastic strain) and the true ultimate stress  $\sigma_u$  at RT and at  $150 \text{ }^\circ\text{C}$ . Only one value of  $\sigma_{p0.2}$  and  $\sigma_u$  is taken by temperature, independent of strain rate.

Figure 11 shows the dependence of the fracture strain on strain rate and on temperature in Inconel 718.

The ductility of Inconel 718 is higher than the ductility of the Ti alloys studied in this work (Ti-6Al-4V and Ti5553). The ductility of Inconel 718 is independent of strain rate and of temperature. Contrarily to the Ti alloys, the dispersion between the different fracture strains  $\epsilon_f$  is very small. Indeed, the minimum and the maximum values of  $\epsilon_f$  are, respectively, equal to 0.46 and 0.508, which leads to an average value equal to  $0.48 \pm 0.025$ .

### 5.2 Model Description

The bolted component is simulated using the finite element software Abaqus (Ref 63), in two steps. In the first step, the bolt is

tightened, with a resulting force of 17 kN, taking advantage of the “bolt load” method of Abaqus standard. In the second step, the tightening is preserved and a displacement is imposed at the external upstream stator surface while the external downstream

Fig. 12 Position of the different strain gages (J1 → J19)

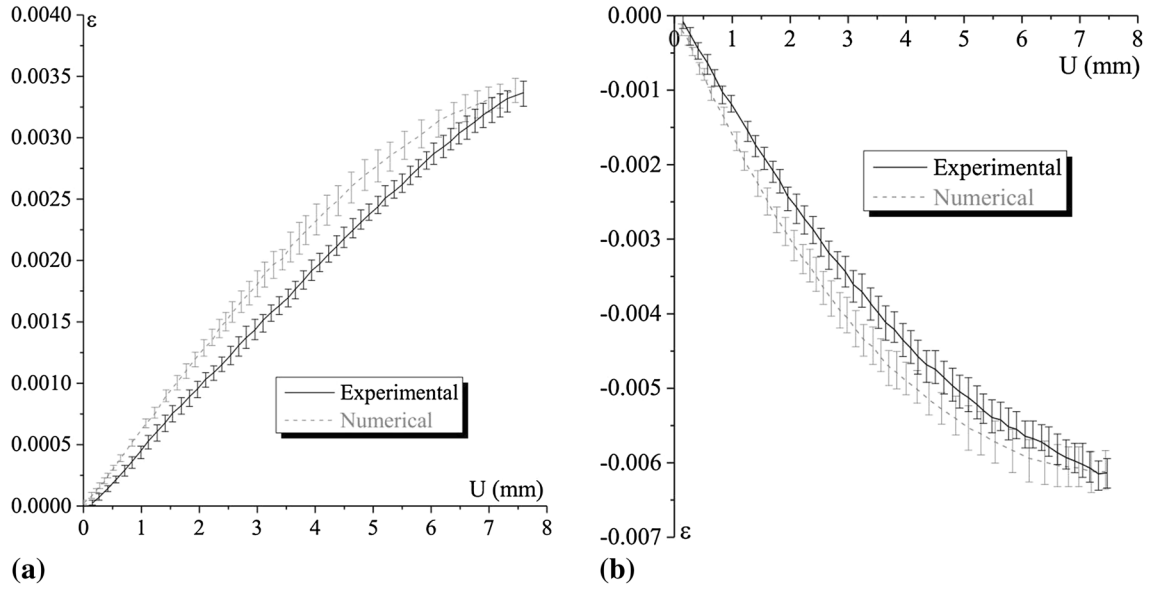

Fig. 13 Comparison between experimental and numerical results: average global tensile force  $F$ -displacement curve on the bolted sector  $U$

**Fig. 14** Comparison between experimental and numerical results from gage number 1: (a) evolution of the maximum strain  $\varepsilon$  as a function of displacement and (b) evolution of the minimum strain  $\varepsilon$  as a function of displacement

stator surface is clamped as depicted in Fig. 9(b). The displacement is imposed at a constant velocity of  $4.5 \times 10^{-3}$  mm/s which corresponds to the velocity imposed in the experiments performed on identical Ti-6Al-4V components.

The Norton-Hoff material law is used with Abaqus through a UHARD interface in order to model the flanges. Note that with the Norton-Hoff law, the yield stress value tends toward zero when the strain rate tends to zero. In order to avoid immediate onset of plasticity at the beginning of the simulation, the minimum allowed strain rate for the yield stress evaluation is imposed to be  $10^{-5}$  s $^{-1}$  which corresponds to the lowest velocity used in the material tests. The evaluation of the fracture criterion is carried out by post-processing the results at the end of each time increment using a Python script. Post-processing consists in evaluating the components of the Thomason criterion of Eq 15 on the basis of the strain and stress values and of the parameters of the damage model calibrated in section 4.4. In order to assess the risk of failure, a new state variable is introduced. This “damage indicator” is computed at each integration point and at the end of each time increment. It is defined based on the comparison of the left and right members of Eq 15:

$$\text{damage indicator} = \begin{cases} 0 & \text{if } \frac{(2/3)T + 1}{1 - \chi^2} < \alpha \left( \frac{1 - \chi}{\chi W} \right)^2 + 1.24 \frac{1}{\sqrt{\chi}} \\ \frac{(2/3)T + 1}{1 - \chi^2} - \alpha \left( \frac{1 - \chi}{\chi W} \right)^2 - 1.24 \frac{1}{\sqrt{\chi}} & \text{otherwise} \end{cases} \quad (\text{Eq 15})$$

The damage indicator is equal to zero as long as coalescence is not reached and equal to the difference between the left and the right hand sides of Eq 15 after coalescence.

The mesh contains  $\sim 120 \times 10^3$  s order tetrahedral elements with a typical size of  $\sim 0.75$  mm locally around the bolt. This

**Fig. 15** Displacement fields in the direction  $x$  at a force level equal to 10,437 N, correlation between numerical prediction and experimental tests: (a) numerical prediction, (b) experimental test number 1, (c) experimental test number 2, and (d) experimental test number 3

mesh was shown to provide converged results while maintaining a reasonable CPU time. Three finite elements are used through the thickness to capture the bending behavior. Contact between the two flanges and between the flanges and the bolt is taken into account using Coulomb static friction. The friction coefficient is equal to 0.4 for all contacts which avoids relative sliding of the different bodies during the simulation.

**5.3 Validation of the Norton-Hoff Model on the Industrial Application: Comparison Between the Experimental Results and the Numerical Predictions**

Several experimental tests have been performed on bolted sectors of a stator component (see Fig. 12) at the University of Liège. To gather as many data as possible in order to compare numerical predictions and experiments, both digital image correlation and strain gages were used to estimate the deformation fields. A stereoscopic technique has been used to measure the displacement (Vic3D). Reaction forces were recorded by load cells. The mean values and standard deviation have been extracted when analyzing the data and representative field histories. The results are given in the following form:

- force/displacement response
- maximum/minimum principal strain in the area of the different strain gages
- mean displacements in each direction

- images of the displacement in the x-direction at two levels of deformation when possible.

**5.3.1 Global Validation.** Figure 13 compares the experimental versus predicted overall force/displacement responses. The experimental result is a mean curve extracted from three different tests. Maximum and minimum values are indicated by error bars. A very good agreement between experimental measurements and numerical predictions is observed at this global level.

**5.3.2 Local Validation.** The focus is first on the minimum and maximum strain levels measured by gage 1 and on the comparison with the numerical predictions (see Fig. 12 for the identification of the position of gage 1). The experimental curve of Fig. 14 is constructed in the same way as the curve of Fig. 13 while the numerical curve is determined as the average of the different curves over the different integration points of the zone corresponding to the gage position. Figure 14 shows the evolution of (a) the maximum and (b) minimum values (involving error bars) as function of the displacement, with a relatively good agreement between the predictions and experimental data. A similar agreement between experiments and predictions is obtained with the other gages. Figure 15 compares the numerically predicted displacement field at a given force level compared to the experimental displacement field determined by stereoscopy at the same force level, showing again a good match. The numerical force level is chosen equal to 10,437 N in order to conform to the experimental force.

**Fig. 16** Fracture of the aircraft engine stators: comparison between the experimental results and the numerical predictions for the force level when experimental rupture occurred (Ti-6Al-4V): (a) experimental result, (b) the numerical damage indicator (back view), and (c) the numerical damage indicator (front view)

## 5.4 Prediction of the Mechanical Response of an Aircraft Engine Stator

In order to predict the mechanical response of an aircraft engine stator, the micromechanical damage model proposed and calibrated in section 2 is used to compare both Ti-6Al-4V and Ti5553 materials. The damage is attained when the coalescence condition of Eq 15 is fulfilled. The possible fracture of the Inconel 718 bolt is ignored here (i.e., this alloy is assumed to have an elastoviscoplastic behavior without damage). The fracture of Inconel 718 is not an issue as the design used in the testing configuration was such it would not induce cracking in the bolts.

(a)

(b)

(c)

**Fig. 17** Comparison between the different titanium alloys: numerical prediction of the damage indicator at an external force of 12,066 N: (a) Ti-6Al-4V (back view), (b) Ti5553-1 (back view), and (c) Ti5553-3 (back view)

Most of the high stress values are supported by the flanges in the vicinity of the bolt. The maximum strain level measured in the upstream flange is a factor 2 larger than the maximum strain level measured in the downstream flange. For these reasons, attention is focused on the upstream flange in the following analysis.

Figure 16(a) shows an experimental image of the component after fracture while Fig. 16(b) and (c) correspond to contour plot of the damage indicator at the instant when the force (in the computation) reaches the value of the force at failure (in the experiment). In these figures, the black color refer to elements in which the damage criterion is not verified (damage indicator = 0). However, the other colors (different from black color) refer to elements where damage is accumulating. Figure 16(b) and (c) shows that failure is attained in a small zone at this force level. Furthermore, comparison between tests and simulations indicates that the failure scenario of the components is relatively well respected with failure occurring in the same region.

In order to compare the performances of Ti-6Al-4V with Ti5553 and to evaluate the potential for replacing the first by one of the latter, several simulations have been performed at RT. The results are presented in Fig. 17. The damage indicator is represented at an external force of 12,066 N (which corresponds to the experimental force of failure of the alloy Ti-6Al-4V) for the different alloys. From this figure, it is not obvious to find a trend about which material would be more prone to fail, proving that there are no negative signs for considering the alloy Ti5553 in this application. Moreover, the

experimental data on Ti-6Al-4V components are quite dispersed and averaged values had to be taken.

## 6. Conclusions

Several experimental tests have been carried out in order to study and to analyze fracture by nucleation, growth, and coalescence of voids in three different titanium alloys. The experiments show that the ductility of Ti-6Al-4V is higher than the ductility of two different Ti-5553 microstructures. The experimental fracture strain exhibits large dispersions. This dispersion is probably induced by uncontrolled local heterogeneities in grain size, texture, or  $\alpha$  macrozones. A damage model has been developed and the corresponding material parameters have been calibrated. This model describes the three main damage phases: void nucleation (Beremin model), void growth (Rice and Tracey model), and void coalescence (Thomason model). The model indicates that the significantly larger fracture strain in the Ti5553-3 microstructure compared to the Ti5553-1 microstructure is the result of a better resistance to void nucleation. The calibrated elastoviscoplastic parameters are used in complex simulations of a bolted sector of an aircraft engine stator in order to compare the numerical force predictions with experimental results. These comparisons are satisfactory. They validate the model for further applications and prove the potential for using the Ti5553 alloy in similar components.

## Appendix 1: Additional Data on Inconel 718 Alloy

### General Description

Inconel 718 alloy is a high-strength, corrosion-resistant nickel chromium material. This alloy is used for jet engine and high-speed airframe parts such as wheels, buckets, spacers, and high temperature bolts and fasteners.

### As-Received Material

The material used for the current study is an Inconel 718 alloy received from Techspace Aero in the form of round bar with a diameter equal to 40 mm and a length equal to 150 mm.

### Heat Treatment

The heat treatment used to generate Inconel 718 alloy is defined by the heat cycles of Fig. 18(a).

A detailed description of the heat treatment cycle is given in the following points:

- heat from room temperature up to a temperature between 941 and 1010 °C.
- hold at the latter temperature during a sufficient time dependent on the thickness of the received material.
- air cooling.
- aging at 732° C during 8 h.
- cooling with a constant temperature rate equal to 56 °C/h up to a temperature between 621 and 649 °C.
- aging at the last temperature during 48 h.
- air cooling.

### Chemical Composition

The chemistry of Inconel 718 alloy used in this study is reported in Table 11.

### Microstructure of Inconel 718 Alloy

The typical microstructure of Inconel 718 alloy is given in Fig. 18(b).
