Keywords: Thermodynamic-based damage model, Natural fiber composites, Damage evolution.

Abstract

The main objective of this preliminary investigation is to identify and characterize the damage evolution of angle ply ($[\pm 45]_{16}$) flax-reinforced epoxy composites using an energy-based damage model combined with Scanning Electron Microscopy (SEM) observations. The damage model's parameters for the flax-reinforced epoxy composite were determined from quasi-static and fatigue tests. The preliminary results showed that the energy-based damage model is able predict accurately the damage rate in both longitudinal and transverse directions for loads. The mechanism of damage initiation in the flax/epoxy composites and the damage evolution, during each test, were monitored using SEM. A direct correlation between the microstructure of the flax-reinforced epoxy composites and the damage was obtained.

Introduction

Natural fibers such hemp, jute, and flax have attracted the attention of many researchers because of their potential to substitute synthetic fibers [1–4]. Since, the use of natural fiber composites in structural applications is fairly new, knowing the mechanical behavior of such materials, in particular, the fatigue life and damage accumulation is crucial in designing new natural fiber-based composite structures with high performances.

Unlike most engineering materials which exhibit a safe stress level called fatigue limit (or endurance limit) below which failure does not occur, fiber-reinforced polymer composites (FRPC) do not typically have such limit. Instead, they undergo a damage accumulation due to matrix cracking, delamination, interface fiber/matrix degradation, fiber breakage, etc. This damage accumulation phenomenon takes place during the entire material's life leading eventually to the progressive failure of the composite even at low applied stresses. The aim of this study is, therefore, to investigate and model the fatigue damage of flax fiber reinforced composites using thermodynamic-based damage model.

Materials and Methods

Flax/epoxy prepreg was purchased from LINEO, Belgium. The product type is a unidirectional (UD) flax fiber treated by a patented sizing and drying process (US Patent No. 8080288) and impregnated with partially cured epoxy resin system (Huntsman LY5150). The flax/epoxy prepreg has an area density of 180 g/m² with an epoxy content of 50 % per weight. Flax/epoxy laminate plates were manufactured using 16 layers of 300 mm X 300 mm sheets with ply [± 45]₁₆ orientation and. The material was placed on a plate in a sealed vacuum bagging set-up and cured in an autoclave at 150°C for 2h under 4 bar pressure while a 0.7 bar vacuum was maintained during the entire cure cycle. The tested specimens were 25 mm width, 250 length and 3 mm thickness.

Tension-tension fatigue tests were conducted on a servo-hydraulic MTS test machine equipped with a 100 kN load-cell capacity. Strain measurements were obtained using an extensometer with a 25 mm gage length, placed at the center of all specimens. Fatigue experiments were conducted in accordance with the ASTM standard D3479 at room temperature and under load control with a minimum to maximum stress ratio of 0.1 and a cyclic frequency of 5Hz. The fatigue limit was assumed to be reached for all tests that did not produce fatigue failure after 6 million cycles.

Fatigue damage model formulation

A fatigue damage model is developed through a phenomenological approach in the framework of thermodynamics. Based on the Ladevèze and Le Dantec work [1], the proposed model takes into account the damage stages characterizing the fatigue damage in natural fiber reinforced polymer matrix composites. Indeed, in such materials, the fatigue damage kinetic occurs according to three stages [2]: i) damage initiation corresponding to an important stiffness reduction during the early stage of damage evolution, namely the first thousands of cycles. ii) Coalescence and propagation of micro-cracks. This second stage is characterized by a behaviour accommodation and a relative steady damage evolution reduction. iii) Macroscopic cracks propagation, damage localization up to the final material failure. According to the continuum damage mechanics, the damage is introduced as an internal state variable coupled to elastic behaviour. The proposed damage model has been formulated through five damage variables [3-4] but in the present paper, only the formulation for in-plane damage involving three variables: d_{11} , d_{22} and d_{12} is considered. Assuming a thin structure (in-plane stress) where $s_{33}=0$, made of an orthotropic material, elastic moduli of the damaged material are then expressed as follows:

$$\begin{aligned} E_{11} &= E_{11}^0 (1 - d_{11}) \\ E_{22} &= E_{22}^0 (1 - d_{22}) \\ G_{12} &= G_{12}^0 (1 - d_{12}) \end{aligned} \quad (1)$$

E_{11} (resp. E_{22}) is the Young's modulus in the longitudinal (resp. transverse) direction. G_{12} is the in-plane shear modulus. d_{ij} are the damage variables associated to the corresponding moduli. The superscript 0 indicates initial values measured when $d_{ij}=0$.

For a damaged material, the elastic strain energy is dependent on the state variables d_{ij} . Then, the strain energy (W_d) of a damaged material is given by equation (2):

$$\begin{aligned}
W_d = & \frac{1}{2} \frac{1}{1-\nu_{12}\nu_{21}} \left[E_{11}^0 (1-d_{11}) \varepsilon_{11} \langle \varepsilon_{11} + \nu_{21} \varepsilon_{22} \rangle_+ + E_{11}^0 \varepsilon_{11} \langle \varepsilon_{11} + \nu_{21} \varepsilon_{22} \rangle_- \right] \\
& + \frac{1}{2} \frac{1}{1-\nu_{12}\nu_{21}} \left[E_{22}^0 (1-d_{22}) \varepsilon_{22} \langle \varepsilon_{22} + \nu_{12} \varepsilon_{11} \rangle_+ + E_{22}^0 \varepsilon_{22} \langle \varepsilon_{22} + \nu_{12} \varepsilon_{11} \rangle_- \right] + G_{12}^0 (1-d_{12}) \gamma_{12}^2
\end{aligned} \tag{2}$$

Where $\langle A \rangle_+$ and $\langle A \rangle_-$ stand for the positive and negative parts of A, respectively.

The damage affects E_{11} when $\varepsilon_{11} + \nu_{21} \varepsilon_{22}$ is positive and E_{22} when $\varepsilon_{22} + \nu_{12} \varepsilon_{11}$ is positive. For instance, when the composite is subjected to a longitudinal compressive loading, transverse cracks do not initiate damage and thus they don't have any effects on the damage evolution of the composite.

The dual thermodynamic variables Y_{ij} associated with the damage variables d_{ij} are deduced from the elastic strain energy W_d of the damaged material as follows:

$$\begin{aligned}
Y_{11} &= -\frac{\partial W_d}{\partial d_{11}} = \frac{1}{2} \left[\frac{1}{1-\nu_{12}\nu_{21}} E_{11}^0 \varepsilon_{11} \langle \varepsilon_{11} + \nu_{21} \varepsilon_{22} \rangle_+ \right] \\
Y_{22} &= -\frac{\partial W_d}{\partial d_{22}} = \frac{1}{2} \left[\frac{1}{1-\nu_{12}\nu_{21}} E_{22}^0 \varepsilon_{22} \langle \varepsilon_{22} + \nu_{12} \varepsilon_{11} \rangle_+ \right] \\
Y_{12} &= -\frac{\partial W_d}{\partial d_{12}} = \frac{1}{2} G_{12}^0 \gamma_{12}^2
\end{aligned} \tag{3}$$

In the present paper, the damage rate describing the damage kinetic with respect to the cycle number and is formulated as a sum of two components:

$$\dot{d}_{11} = \frac{\partial(d_{11})}{\partial(N)} = \frac{\alpha_{11} \beta_{11}}{1 + \beta_{11}} (Y_{11})^{\beta_{11}-1} + \lambda_{11} (Y_{11}) \left(e^{-(\delta_{11} N)} \right) \tag{4}$$

$$\dot{d}_{22} = \frac{\partial(d_{22})}{\partial(N)} = \frac{\alpha_{22} \beta_{22}}{1 + \beta_{22}} (Y_{22})^{\beta_{22}-1} + \lambda_{22} (Y_{22}) \left(e^{-(\delta_{22} N)} \right) \tag{5}$$

$$\dot{d}_{12} = \frac{\partial(d_{12})}{\partial(N)} = \frac{\alpha_{12} \beta_{12}}{1 + \beta_{12}} (Y_{12})^{\beta_{12}-1} + \lambda_{12} (Y_{12}) \left(e^{-(\delta_{12} N)} \right) \tag{6}$$

The first contribution, scaled by $(Y_{ij})^{\beta_{ij}-1}$ in equations (4) to (6), is derived from the Norton power law that describes the dissipation potential. The second component is introduced to describe the rapid stiffness reduction occurring during the cyclic loading. The state variables $d_{ij}(N)$ are obtained by numerical integration of the damage rates, with the initial conditions $d_{ij}(N=0) = d_{ij}^{qs}$.

Where d_{ij}^{qs} stands for the initial damage induced during the first loading ramp prior to the cyclic loading. These initial values are function of the applied stress level.

The developed fatigue damage model requires 12 parameters to be identified namely, four parameters per damage variable. In this work, the model is developed for tension-tension fatigue loading and hence 4 parameters have to be identified.

Fig. 1. Load history obtained from a force controlled fatigue test. Note that quasi-static preloading ramp (prior to the point S) gives rise to an initial damage representing the quasi-static damage (denoted by d_{qs}).

Model damage parameters identification procedure

An identification method involving homogeneous tensile fatigue tests have been used to determine the longitudinal damage parameters. The goal is to identify the parameters involved in the damage evolution, for the longitudinal direction (α_{11} , β_{11} , λ_{11} and δ_{11} governing the damage d_{11}). For this purpose, load control tension-tension fatigue tests on composite specimens have been performed in longitudinal direction [2]. These fatigue tests have been carried-out at three stress levels: $\sigma_{max} = 65\% \sigma_{UTS}$, $\sigma_{max} = 70\% \sigma_{UTS}$ and $\sigma_{max} = 80\% \sigma_{UTS}$. The applied stress ratio $R = \sigma_{min} / \sigma_{max}$ remains constant for the different configuration ($R = 0.1$) and the frequency was fixed up to 5Hz.

The identification procedure relies on a cost function $S(P)$ that has been built as an objective function representing, in the least squares sense, the difference between experimental and computed damage values. It has been minimized using the gradient-based Levenberg-Marquart (LM) algorithm [5-7] which can be written as follows:

$$S(\underline{P}) = \frac{\sum_{i=1}^a [d_i^{exp}(\underline{P}) - d_i^{num}]^2}{\sum_{i=1}^a (d_i^{exp})^2} \quad (7)$$

Where a is the number of experimental data. d_i^{exp} denotes the experimental damage values determined using the dynamic modulus reduction curve (**Fig. 3**): $d_i^{exp} = 1 - E_i(N) / E_0$. d_i^{num} are the computed damage values predicted by the developed model. \underline{P} is the unknown parameter vector that contains the model parameters (α_{11} , β_{11} , λ_{11} , δ_{11}).

The minimisation of the cost function consists of an iterative procedure. At each step, a new solution increment ΔP is computed using the LM algorithm and the solution vector P is then re-estimated (P becomes $P + \Delta P$) and the cost function S is re-evaluated. The iterative procedure is stopped once two consecutive values of the cost function satisfy the relationship below (namely, when the cost function becomes stationary [8-9]).

$$\|S(P + \Delta P) - S(P)\| \leq 10^{-5}$$

The damage parameters (α_{11} , β_{11} , λ_{11} , δ_{11}) were identified using experimental data obtained from the fatigue test corresponding to $\sigma_{\max} = 70\% \sigma_{UTS}$ and are summarized in **Table 1**.

Table 1. Damage model parameters identified from experimental fatigue tests at $\sigma_{\max} = 70\% \sigma_{UTS}$.

Parameters	α_{11}	β_{11}	λ_{11}	δ_{11}
$[\pm 45]_{4s}$ Flax epoxy composite	2.51E-3	5.6	3.95E-3	2.21E-2

Results and discussion

The maximum and minimum strains for $[\pm 45]_{4s}$ angle ply laminates are presented in **Fig. 2**. As can be seen, the strain increases rapidly in the early part of the test, and then it increases with a constant slope followed by an acceleration of the strain before failure. The analysis of the SEM images shows a very good concordance between the evolution of the cracks inside the composite and the increase of the strain (see **Fig. 5**).

Fig. 2. Mean and maximum strain versus the normalized number of cycles for angle ply laminates at different loading conditions.

The normalized dynamic modulus (E^*/E_0) was determined for $[\pm 45]_{4S}$ angle ply composite laminates at different applied stress levels by calculating the slope of the linear part of the strain vs. stress curve at each cycle. The normalized dynamic modulus for $[\pm 45]_{4S}$ laminates are plotted against the normalized number of cycle (Cycle N / total cycles to failure N_f) and presented in **Fig. 3**. The normalized dynamic modulus was found to decrease with number of cycles until failure according to three stages. In stage 1, rapid stiffness degradation was observed during the first thousands of cycles, followed by (stage 2) a progressive decrease of the dynamic modulus during almost the entire life of the laminate (more than 80% N/N_f). In the third stage, accelerated stiffness reduction leading to the total material failure was observed.

Fig. 3. Normalized dynamic modulus (E^*/E_0) versus the normalized number of cycles for angle ply laminates at different loading conditions.

The S-N curve and the high cyclic fatigue strength (HCFS) of $[\pm 45]_{4S}$ angle ply flax/epoxy composite laminates were determined using stepwise loading fatigue tests. The stress (in terms of % of the ultimate tensile strength (UTS)) as a function of the number of cycles to failure is shown in **Fig. 4**. The HCFS (or endurance limit) of angle ply composite laminates varies between 57% and 59% of UTS. A comparable value determined using infrared thermography was reported previously [2]. The failure of the $[\pm 45]_{4S}$ composite laminates occurred at 85% of the UTS.

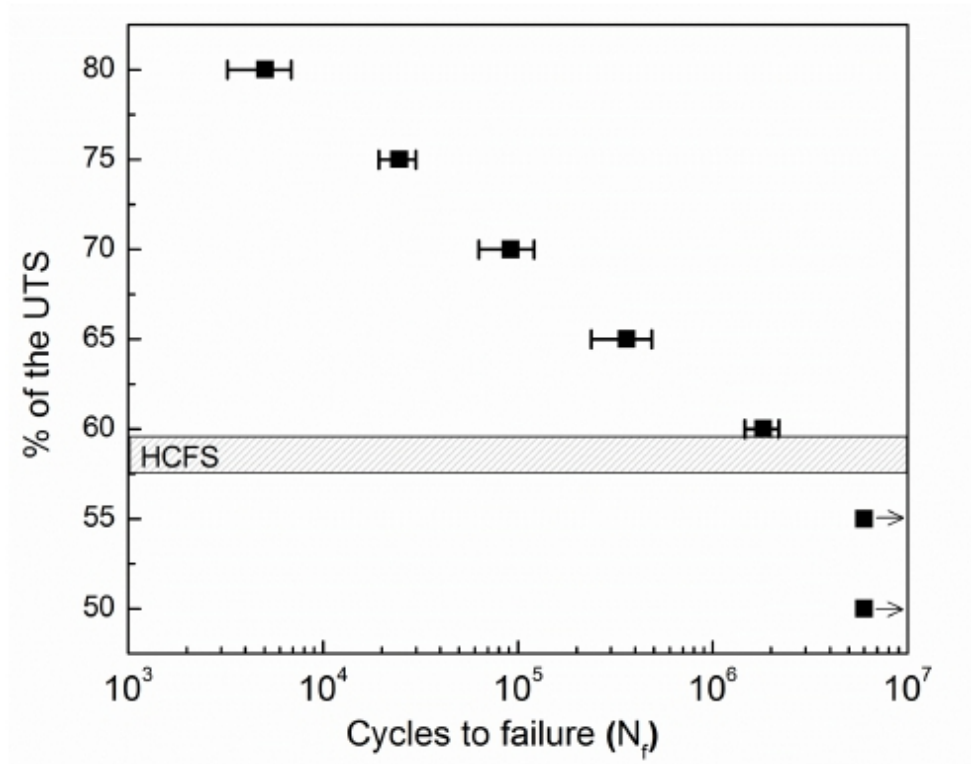

Fig. 4. S-N curve showing HCFS for $[\pm 45]_4s$ laminates

SEM observations at 80% of UTS for $[\pm 45]_4s$ angle ply composite laminate distinguished three main fatigue micro-damage mechanisms (Fig. 5). At the beginning of cycling (i.e., $1/3 N_f$), the micro-cracks initiated inside the bundle of flax fibers bonded together by pectin, then these micro-cracks nucleate inside the bundles between fibers. With the increased loading ($2/3 N_f$), the cracks continue to grow slightly and propagate inside the bundle (from one end to the other) without further propagating in the matrix rich area. At the total failure of the laminate the micro-cracks appear to have further grown in the bundles with subsequent propagation in the matrix and the number of cracks (or density of crack) is considerable.

Fig. 5. SEM images for $[\pm 45]_4s$ angle ply laminates at 80% UTS load at (a) the beginning of cycling ($1/3$ of N_f) and b) just before failure

For the fatigue damage model proposed, the set of the damage parameters identified through the inverse procedure from experimental fatigue tests performed at $\sigma_{\max} = 70\% \sigma_{\text{UTS}}$ were included into the fatigue damage model to predict the damage evolution for different applied stress levels of $\sigma_{\max} = 65\% \sigma_{\text{UTS}}$ and $\sigma_{\max} = 80\% \sigma_{\text{UTS}}$. The comparison between experimental data used for the identification strategy and the computed damage curves are presented on **Fig.6**. One can note that a good correlation between experimental and computed damage evolutions is obtained for both stress levels notably for the fatigue test at $\sigma_{\max} = 65\% \sigma_{\text{UTS}}$. This demonstrates that the proposed model is thus able to take into account the damage evolution of angle ply $[\pm 45]_{4s}$ flax fiber-reinforced polymer laminates under cyclic loading. However, it is worth noting that for fatigue tests at $\sigma_{\max} = 80\% \sigma_{\text{UTS}}$ and for a number of cycles up to 70% of N_f , the model predictions do not fit the experimental damage curve. This is mainly due to the damage localization phenomenon occurring once macroscopic cracks propagate till the final failure of the composite material. In fact, SEM observations (**Fig. 5**) showed that for high-applied stress level (up to $80\% \sigma_{\text{UTS}}$) and high fatigue life (up to 70% of N_f), a significant increase of the crack density was observed in the composite specimens which in turn may lead to a dramatic damage accumulation and a rapid reduction in the composite' stiffness leading to the total failure of the composite laminate.

Fig. 6. Comparison between experimental and computed damage evolution for tension-tension fatigue tests at different loading levels. Predicted damage curves agree well with experimental results as long as the damage remains diffuse. No damage localization phenomenon occurs up to 70% of fatigue life.

The evolution of the longitudinal damage rate versus the normalized number of cycles is plotted in Fig.7. Because the damage rate values for 80% load of UTS are 10 times higher than those for 65% and 70% load of UTS, two different scales were used for a better presentation of the damage rate. As can be seen, the damage rates increased slightly with a constant slope for loads below or equal 70% of UTS and it increased drastically for high loads up to 80% of UTS. As it was mentioned before, this can be explained by the fact that the damage remains diffuse for low and moderate loads leading to a steady stable damage rate. However, for high loads and high fatigue life (up to 70% of N/N_f), the damage and the damage rate are more pronounced due to the coalescence of the cracks.

Fig. 7. Damage rate evolution as a function of the normalized number of cycles (N/N_f)

Conclusion

In this investigation, we have demonstrated that the thermodynamic-based damage model can capture the damage evolution and its rate in $[\pm 45]_4s$ angle ply composite laminates as long as the damage remains diffuse. Based on the fatigue tests and SEM observations, the damage in flax/epoxy laminates initiates in a form of micro-cracks inside the fiber bundles between fiber-fiber interfaces suggesting that the bonding resin is the weakest part in the flax/epoxy composite. These micro-cracks propagate through the interface between the elementary fibers within the bundles during cyclic loading leading to the formation of macroscopic cracks and the progressive failure of the flax composite.
