Abstract

This paper deals with vibration control by means of piezoelectric patches shunted with electrical impedances made up by a resistance and a negative capacitance. The paper analyses most of the possible layouts by which a negative capacitance can be built and shows that a common mathematical description is possible. This allows closed formulations to be found in order to optimise the electrical network for mono- and multi-mode control. General analytical formulations are obtained to estimate the performance of the shunt in terms of vibration reduction. In particular, it is highlighted that the main effect of a negative capacitance is to artificially enhance the electromechanical coupling factor, which is the basis of performance estimation. Stability issues relating to the use of negative capacitances are especially addressed using refined models for the piezoelectric patch capacitance. Furthermore, a new circuit based on a couple of negative capacitances is proposed and tested, showing better performances than those provided by the usual layouts with a single negative capacitance. Finally, guidelines and analytical formulations to deal with the practical implementation of negative capacitance circuits are provided.

Keywords: piezoelectric shunt, negative capacitance, vibration control, damping, smart structure

(Some figures may appear in colour only in the online journal)

1. Introduction

The use of piezoelectric actuators shunted with electric impedances in order to damp structural vibrations is an attractive approach because such lightweight control devices do not cause high load effects and require little or no power supply to control the structure. Such control methods can be classified as passive if the electric components used to practically build the impedance are passive (e.g. composed of a single resistance (resistive (R) shunt) or the series of a resistance and an inductance (resonant (RL) shunt)) [1], semi-passive if the electronic circuit needs to be powered but is still theoretically equivalent to a passive one (in the case of a synthetic inductance, for instance) [2], or active. The most common example of an active circuit in the context of

piezoelectric shunt is the negative capacitance (NC), practically realised with an operational amplifier (OP-AMP). The use of NCs enables the attenuation performance of the shunt to be increased [3, 4], but poses some issues relating to possible instabilities in the electro-mechanical system (EMS) because of its active nature.

Some aspects relating to the use of NCs to enhance the performances of shunted piezoelectric actuators have been addressed in the literature. Indeed, the use of circuits based on OP-AMPs to shunt piezoelectric actuators has been described in different pieces of work (e.g. [5]). Among the different circuits proposed, the NC was shown to be effective for vibration control. De Marneffe and Preumont [3] analysed the simplest layouts, named ideal circuits (IC) here, to build the NCs, and gave the stability criteria. In contrast, other authors

have focused on more complex circuits, named real circuits (RC) here, because they are more reliable for practical implementation. The RCs cannot be considered as pure NCs (see section 5) but as complex negative impedances, while ICs can be seen as pure NCs. Behrens *et al* [4] considered an RC and showed its capability to provide broadband vibration attenuation when shunted to piezoelectric actuators. Park and Baz [6] shunted a pair of interdigital electrode piezoceramics with an NC to achieve broadband vibration control for a cantilevered beam. The works of Behrens *et al* and of Park and Baz differ in how to shunt the NC to the piezoelectric element (series and parallel respectively). Manzoni *et al* [7] analysed the stability of an RC in a series layout and Kodejška *et al* [8] used an RC in a series configuration in an adaptive circuit for the purpose of vibration isolation. Beck *et al* proposed an electrical model of an RC in a series layout in [9] and presented a procedure for improving the attenuation performance provided by an RC in a series configuration in [10].

An NC can be coupled to any passive (or semi-passive) shunt in order to increase its performance—especially the traditional R- and RL-shunts. The latter solution allows the attenuation provided by the pure resistive shunt to be improved a lot, despite losing its robustness [11]. The idea followed in this article is to use a negative capacitance to increase the attenuation performance of a pure resistive shunt while keeping its robustness. This article also addresses a tuning strategy to obtain multi-mode attenuation by means of a negative capacitance resistive shunt, whereas vibration attenuation is localised in a narrow frequency band around a given resonance for traditional R and RL shunts.

One of the purposes of the paper is to propose and analyse a new shunt impedance configuration based on two NCs, in order to enhance the performance of traditional NC circuits coupled to a resistive shunt. In doing so, traditional layouts for NCs are reconsidered here. Indeed, although the use of an NC with a resistive shunt has already been described in the literature, no clear criteria for tuning the electric parameters and optimising shunt performance are available. Furthermore, different layouts can be used to practically build an NC circuit as mentioned previously, and some of them are seldom taken into account or analysed in the literature. Finally, no clear evaluation of the possible performances attainable with a negative capacitance are available. Therefore, for all the above-mentioned issues, the main targets of this paper are (i) to analyse most of the possible practical NC configurations, showing that a common analytical treatment can be used (see section 2); (ii) to propose a refined model for piezoelectric patch capacitance in order to derive accurate stability limits when NCs are used and to achieve a more accurate description of EMS behaviour (refer to sections 2 and 6); (iii) to propose a new layout based on the use of two NCs able to guarantee better vibration attenuation with respect to the traditional NC layouts (see section 3); (iv) to provide clear optimisation formulas to be employed in order to reach the highest possible attenuation for both mono-modal and broadband attenuation and (v) to derive analytical formulas which foresee the attenuation performance of the shunt,
Figure 1. An arbitrary structure with a piezoelectric patch connected to a shunt impedance Z.

valid for any NC configuration (refer to section 4); finally, (vi) to study the behaviour of RCs and compare it to that of ICs, for practical implementations (see section 5). To conclude, all the aforementioned theoretical results are validated by experiments (refer to section 6).

2. Model of the electro-mechanical system

2.1. Governing equations

The model employed to describe the behaviour of the EMS is the one presented in the paper of Thomas *et al* [2], which was used by its authors to find the optimal tuning of R and RL impedances shunted to a piezoelectric actuator as well as the associated vibration attenuation performances. We consider an arbitrary elastic structure with one piezoelectric patch bonded to it and excited by an external force (named F_{ext}), shown in figure 1. An arbitrary shunt impedance Z is connected to the piezoelectric patch and V is the voltage between the electrodes of the piezoelectric actuator, which is also the shunt terminal voltage. Q is the electric charge in one of the electrodes, and considering the convention of the sign for V in figure 1, Q is precisely the charge in the upper electrode. A reduced order model can be obtained by expressing the displacement $U(x, t)$ at any point x and time t in modal coordinates and considering the N vibration eigenmodes (N being infinite in theory):

$$U(x, t) = \sum_{i=1}^{N} \Phi_i(x) q_i(t) \qquad (1)$$

where Φ_i is the ith eigenmode of the structure (normalised to the unit modal mass) and q_i is the ith modal coordinate. The modal coordinates $q_i(t)$ are the solutions to a problem of the form [12, 13]:

$$\ddot{q}_i + 2\xi_i \omega_i \dot{q}_i + \omega_i^2 q_i - \chi_i V = F_i \qquad \forall i \in 1 \dots N \quad (2a)$$

$$C_\infty V - Q + \sum_{i=1}^{N} \chi_i q_i = 0 \qquad (2b)$$

In the above equations, ω_i denotes the ith natural frequency of the EMS in short circuit (SC, i.e. with $Z = 0$), ξ_i is the ith structural damping factor, F_i is the harmonic modal forcing term, C_∞ is the electrical capacitance of the piezoelectric patch (its physical meaning will be discussed in section 2.2)

and χ_i is the modal coupling coefficient, which represents the energy transfer between the ith mode shape and the piezoelectric patch. The values of χ_i depend on the electrical, geometrical and mechanical characteristics of the piezoelectric actuator and structure, and on the position of the actuator. These χ_i coefficients can be computed analytically [12] or by a finite element model [13], or estimated experimentally. The writing of equation (2a) relies on a chosen normalisation of the mode shapes to have unit modal masses. The unit of Φ_i is therefore kg$^{-1/2}$, the unit of q_i is m·kg$^{1/2}$, and the one of F_i is N·kg$^{-1/2}$, so that the unit of χ_i is either N·V^{-1}·kg$^{-1/2}$ or C·m^{-1}·kg$^{-1/2}$, depending on whether the direct or converse piezoelectric effects are considered. Note that (Φ_i, ω_i) are the eigenmodes of the EMS with the piezoelectric patch in short circuit (SC) (with $V = 0$) and that C_∞ is the patch capacitance of the blocked structure (with $U(x, t) = 0 \ \forall x \Rightarrow q_i = 0 \ \forall i$). As for a rectangular piezoelectric patch with a constant thickness h, the patch capacitance of the blocked structure can be computed theoretically by [13]:

$$C_\infty = \bar{\epsilon}_{33} S / h \tag{3}$$

where S is the area of the electrodes and $\bar{\epsilon}_{33}$ is the modified dielectric permittivity at constant strain, in the patch transverse direction, of the piezoelectric material.

The EMS is thus described by N modal equations (equation (2a)), corresponding to the balance law of mechanical forces, which describe the equations of motion of the EMS. These equation (2a) are coupled by the term $\chi_i V$ to equation (2b), which represents the electrical behaviour of the system. Equation (2b) is related to the balance of electric charges on the piezoelectric patch electrodes.

2.2. Model of the electrical capacitance and static correction

The piezoelectric actuator and the structure are physically linked, and thus the dynamics of the structure is affected by the electrical behaviour of the EMS through the coupling coefficients χ_i. On the other hand, the electrical behaviour of the system is in turn affected by the dynamics of the structure. Indeed, the expression of an equivalent capacitance can be derived from equations (2a), (2b). The expression of such an equivalent capacitance is frequency-dependent and can be obtained solving equation (2a) with respect to q_i in the frequency domain (with $F_i = 0$) and substituting the result in equation (2b). If all variables oscillate at a frequency Ω, the equivalent capacitance of the EMS is:

$$C(\Omega) = \frac{\underline{Q}(\Omega)}{\underline{V}(\Omega)} = C_\infty + \sum_{i=1}^{N} \frac{\chi_i^2}{\omega_i^2 - \Omega^2 + 2j\xi_i\omega_i\Omega} \tag{4}$$

where j is the complex imaginary unit and $\underline{Q}$ and $\underline{V}$ are the complex amplitudes of Q and V.

The trend of $C(\Omega) = \underline{Q}/\underline{V}$ for a generic system is depicted in figure 2(a). It shows that the value of $C(\Omega)$ decreases after each resonance of the system, because of the second term of equation (4). As for the high frequency range (at frequencies above the highest natural frequency of the EMS), $C(\Omega) \simeq C_\infty$. As a consequence, the capacitance C_∞ of

the blocked structure, which naturally appears in the model (2a), (2b) (see equation (3)), is also the value of the capacitance of the piezoelectric patch at high frequency. In the low frequency range, below the first natural frequency of the EMS, $C(\Omega) \simeq C_0$ with:

$$C_0 = C_\infty + \sum_{i=1}^{N} \frac{\chi_i^2}{\omega_i^2}. \tag{5}$$

If the natural frequencies of the modes are well separated, a single-degree-of-freedom approximation can be carried out to describe the behaviour of the EMS for $\Omega \simeq \omega_i$. Therefore, the second term of equation (4) can be approximated by keeping only the contribution of the ith mode in the sum, so that:

$$\Omega \simeq \omega_i \quad \Rightarrow \quad C(\Omega) \simeq C_\infty + \frac{\chi_i^2}{\omega_i^2 - \Omega^2 + 2j\xi_i\omega_i\Omega},$$
$$\forall i = 1 \dots N \tag{6}$$

This simple one-degree-of-freedom (dof) model is not accurate in describing the behaviour of the capacitance around the mode considered (see figure 2(b)). It can be corrected by adding the low and high frequency contributions of all the modes which are out of the frequency band of interest. At the frequencies Ω around ω_i, the contribution of all the modes n at a lower frequency ($\omega_n \ll \omega_i$) is zero because the corresponding term in the sum of equation (4) tends to zero for $\Omega \gg \omega_n$. All the modes n of higher frequency ($\omega_n \gg \omega_i$) contribute with a static component χ_n^2/ω_n^2, since in this case $\Omega \ll \omega_n$. As a consequence, a refined one-degree-of-freedom model for $C(\Omega)$ is:

$$\Omega \simeq \omega_i \quad \Rightarrow \quad C(\Omega) \simeq C_{\mathrm{p}i} + \frac{\chi_i^2}{\omega_i^2 - \Omega^2 + 2j\xi_i\omega_i\Omega},$$
$$\forall i = 1 \dots N \tag{7}$$

with

$$C_{\mathrm{p}i} = C_\infty + \sum_{n=i+1}^{N} \frac{\chi_n^2}{\omega_n^2}, \qquad \forall i = 1 \dots N \tag{8}$$

In other words, the capacitance value $C_{\mathrm{p}i}$ at a given frequency does not depend on the modes of the structure at lower frequency, but just on those at higher frequency.

As a consequence, a refined one-degree-of-freedom model of the EMS, valid in a frequency band around a given resonance ($\Omega \simeq \omega_i$), is obtained by keeping only the ith mode in the expansion ($q_n = 0, \ \forall n \neq i$). Therefore, equation (1) is replaced by $U(x, t) = \Phi_i(x)q_i(t)$, equation (2a) is kept and equation (2b) is replaced by:

$$C_{\mathrm{p}i} V - Q + \chi_i q_i = 0, \tag{9}$$

where the static correction due to the higher modes is included in the term $C_{\mathrm{p}i}$.

Figure 2(b) shows how it is possible to improve the accuracy of the model of the capacitance using equation (7) in place of equation (6) in the frequency band around the mode taken into account. Figure 2(b) shows that the use of $C_{\mathrm{p}i}$
Figure 2. The trend of $C(\omega) = |\underline{Q}/\underline{V}|$ for a generic, undamped three-degrees-of-freedom system. (a) The complete model of equation (4); (b) zoom showing the complete model (black) of equation (4) and the 1 dof models of equation (6) (dashed lines) and (7) (solid lines) tuned to mode 1 (red) and mode 2 (green). Note that the continuous lines relating to equations (4) and (7) (red line, first mode) are fully superimposed before ω_1.

(equation (7)) leads to a 1 dof model which almost merges with the complete model of equation (4) around a given resonance; this is far from being the case for the classical simple model of equation (6) with C_∞. Figure 2(b) also shows that $C(\Omega)$ assumes the value $C_{\mathrm{p}i}$ almost midway between the resonance frequencies of mode i and $i + 1$.

2.3. Coupling factor

In order to introduce the electromechanical coupling factor, we apply the following changes of variables:

$$\bar{V} = V\sqrt{C_{\mathrm{p}i}}, \qquad \bar{Q} = \frac{Q}{\sqrt{C_{\mathrm{p}i}}} \qquad (10)$$

Substituting equation (10) into equations (2a) and (9), a normalised formulation to describe the EMS behaviour is obtained:

$$\ddot{q}_i + 2\xi_i\omega_i\dot{q}_i + \omega_i^2 q_i - \omega_i k_i \bar{V} = F_i, \qquad (11a)$$

$$\ddot{q}_i + 2\xi_i\omega_i\dot{q}_i + \hat{\omega}_i^2 q_i - \omega_i k_i \bar{Q} = F_i, \qquad (11b)$$

$$\bar{V} - \bar{Q} + \omega_i k_i q_i = 0, \qquad (11c)$$

where:

$$k_i = \frac{\chi_i}{\omega_i\sqrt{C_{\mathrm{p}i}}}, \qquad \text{and} \qquad \hat{\omega}_i = \omega_i\sqrt{1 + k_i^2}. \qquad (12)$$

Equations (11a) and (11b) are equivalent, both expressing the converse piezoelectric effect, as a function of either $\bar{V}$ or $\bar{Q}$. Equation (11b) is obtained by substituting $\bar{V}$ in favour of $\bar{Q}$ in equation (11a) using (11c). The non-dimensional parameter k_i is defined as the modal electromechanical coupling factor (MEMCF). The short- (SC) and open-circuit (OC) natural frequencies of the EMS are ω_i and $\hat{\omega}_i$ (respectively associated

with zero ($Z = 0$) and infinite ($Z = \infty$) shunt impedances, also obtained with $\bar{V} = 0$ and $\bar{Q} = 0$ respectively). Equation (12) shows that the MEMCF k_i is close to the ith effective coupling factor:

$$k_{\mathrm{eff}} = \sqrt{\frac{\hat{\omega}_i^2 - \omega_i^2}{\omega_i^2}} = |k_i| \qquad (13)$$

As suggested in [3, 14], the SC natural frequencies ω_i are the poles of $C(\Omega)$ (equation (4)) and the OC natural frequencies $\hat{\omega}_i$ are its zeros. Since k_i is dimensionless, another unit for χ_i is $\mathrm{F}^{1/2} \cdot \mathrm{s}^{-1}$.

By considering the definition of k_i in equation (12) together with equation (8), it can be derived that the values of $C_{\mathrm{p}i}$ for two consecutive modes in the spectrum are linked by:

$$C_{\mathrm{p}i} = C_{\mathrm{p}\,i+1}(1 + k_{i+1}^2) \qquad (14)$$

Consequently, the value of the capacitance at the null frequency can be derived as a function of all the modes of the structure:

$$C_0 = C_\infty + \sum_{i=1}^{N} C_{\mathrm{p}i} k_i^2 \qquad (15)$$

The following relations for the different capacitance values hold:

$$C_0 > C_{\mathrm{p}\,1} > \dots > C_{\mathrm{p}i} > \dots > C_\infty \qquad (16)$$

These results are illustrated in figure 2(b): the capacitance, out of the resonance zones, changes by a factor almost equal to $C_{\mathrm{p}i} k_i^2$ at each resonance crossing.

2.4. EMS with negative capacitance

Once the model of the EMS (section 2.3) has been described, we can consider the case in which an NC is connected to the piezoelectric actuator, in addition to the shunt impedance, now denoted by Z_{sh}. There are two classical configurations for the NC: a parallel configuration (figure 3(a)) or a series configuration (figure 3(b)). Both layouts are characterised by the presence of an additional negative capacitance $-C_1$ or $-C_2$. This element is theoretically defined by the following relation between its terminal voltage V_c and its charge Q_c (see figure 3(c)):

$$V_c = -\frac{Q_c}{C_n} \quad (17)$$

Since NCs do not exist in nature, they are built in practice by means of a circuit including an OP-AMP [15]. Such a circuit will be discussed in detail in section 5.

In the following, we focus our attention on the response of the EMS due to the ith vibration mode ($q_n = 0 \ \forall n \neq i$), using the model of equation (9) with the static correction. As for the parallel configuration (figure 3(a)), the charge Q is the sum of the charges in the negative capacitance $-C_1$ branch and the shunt impedance Z_{sh} branch, so that equation (2b) is replaced by:

$$(C_{\text{p}i} - C_1)V - Q_{\text{sh}} + \chi_i q_i = 0 \quad (18)$$

As for the series configuration, the voltage V is the sum of the voltages at the terminals of the negative capacitance $-C_2$ and the shunt impedance Z_{sh}, so that equation (2b) is replaced by:

$$V_{\text{sh}} - \left(\frac{1}{C_{\text{p}i}} - \frac{1}{C_2}\right)Q + \frac{\chi_i}{C_{\text{p}i}} q_i = 0 \quad (19)$$

In the above equations, V_{sh} and Q_{sh} denote the terminal voltage across the shunt impedance and the charge that flows into the shunt impedance branch, respectively.

It is now convenient to define the following equivalent capacitances:

$$C_{\text{eqp}} = C_{\text{p}i} - C_1, \qquad C_{\text{eqs}} = \frac{C_{\text{p}i} C_2}{C_2 - C_{\text{p}i}}. \quad (20)$$

These are related to the configuration with $-C_1$ in parallel to the piezoelectric patch and $-C_2$ in series with the piezoelectric patch respectively. By applying a change of variables analogous to that in equation (10):

$$\bar{V}_{\text{sh}} = V_{\text{sh}}\sqrt{C_{\text{eq}}} \qquad \bar{Q}_{\text{sh}} = \frac{Q_{\text{sh}}}{\sqrt{C_{\text{eq}}}} \quad (21)$$

with $C_{\text{eq}} = C_{\text{eqp}}$ or $C_{\text{eq}} = C_{\text{eqs}}$, the initial problem (11a)–(11c) can be rewritten in the following form:

$$\ddot{q}_i + 2\xi_i \omega_i \dot{q}_i + (\omega_i^{\text{sc}})^2 q_i - \omega_i \tilde{k}_i \bar{V}_{\text{sh}} = F_i, \quad (22a)$$

$$\ddot{q}_i + 2\xi_i \omega_i \dot{q}_i + (\omega_i^{\text{oc}})^2 q_i - \omega_i \tilde{k}_i \bar{Q}_{\text{sh}} = F_i, \quad (22b)$$

$$\bar{V}_{\text{sh}} - \bar{Q}_{\text{sh}} + \omega_i \tilde{k}_i q_i = 0 \quad (22c)$$

The above set of equations defines the dynamics of the EMS viewed from the shunt impedance Z_{sh} since the electrical unknowns are now $\bar{V}_{\text{sh}}$ and $\bar{Q}_{\text{sh}}$. The following parameters have been defined: ω_i^{sc} and ω_i^{oc} are respectively the natural frequency of the EMS with the shunt Z_{sh} short-circuited ($V_{\text{sh}} = 0 \Leftrightarrow Z_{\text{sh}} = 0$) and in open-circuit ($Q_{\text{sh}} = 0 \Leftrightarrow Z_{\text{sh}} = \infty$). Their values depend on the values of the negative capacitances $-C_1$ and $-C_2$. The above model characterises the behaviour of the EMS grouped with the negative capacitances $-C_1$ or $-C_2$, whose apparent capacitance is C_{eqp} or C_{eqs}, instead of $C_{\text{p}i}$. A new coupling factor naturally appears in the equations: the enhanced modal electromechanical coupling
Figure 4. The FRFs (equation (26)) of a 1 dof EMS associated with several resistive shunt circuits and several tunings of R_{sh} (τ_e). SC and OC: short- and open-circuit response without a NC; OCP: open-circuit response with a negative capacitance in parallel configuration; SCS: short-circuit response with a negative capacitance in series configuration; R (R-shunt), P (parallel), S (series) and SP (series +parallel): response of the EMS with the optimal value of R_{sh} (τ_e) for each NC layout.

factor (EMEMCF) $\tilde{k}_i$, that can be written as:

$$|\tilde{k}_i| = \sqrt{\frac{(\omega_i^{oc})^2 - (\omega_i^{sc})^2}{\omega_i^2}}, \tag{23}$$

similar to that of equation (13). One can notice that $\tilde{k}_i$ is not exactly the traditional effective coupling factor since now the denominator is ω_i and not ω_i^{sc}. These parameters, which take different values in the parallel and series configurations, are gathered in table 1. Their dependence upon the negative capacitances C_1 or C_2 will be discussed in detail in sections 2.6 and 2.7.

It is worth highlighting that equations (22a)–(22c), which describe the EMS with an NC (series or parallel), are valid even for a simple shunt (without NC). Indeed, it is sufficient to substitute in the model the original ω_i and $\hat{\omega}_i$ in place of ω_i^{sc} and ω_i^{oc} and k_i in place of $\tilde{k}_i$. Therefore, the model described by equations (22a)–(22c) can be considered general and valid for simple and NC shunts.

2.5. Resistive shunt

We now consider a resistance as shunt impedance (i.e. $Z_{sh} = R_{sh}$ in figure 3). This leads to $V_{sh} = -R_{sh}\dot{Q}_{sh}$, so that equation (22c) becomes:

$$\tau_e \dot{\bar{Q}}_{sh} + \bar{Q}_{sh} - \omega_i \tilde{k}_i q_i = 0. \tag{24}$$

With the electrical time constant

$$\tau_e = R_{sh} C_{eq}. \tag{25}$$

One has to remark that τ_e also depends on the considered ith mode because C_{eq} depends on C_{pi}.

Consequently, relying on equations (22b) and (24), the frequency response function (FRF) $H_i(\Omega)$ between a

harmonic modal force F_i of frequency Ω and q_i is:

$$H_i(\Omega) = \frac{q_i}{F_i} =$$

$$\frac{1 + j\tau_e \Omega}{(\omega_i^{sc})^2 - (1 + 2\xi_i\omega_i\tau_e)\Omega^2 + j\Omega[\tau_e(\omega_i^{oc})^2 + 2\xi_i\omega_i - \tau_e\Omega^2]} \tag{26}$$

2.6. Stability conditions for ideal series and parallel circuits

The introduction of active elements such as OP-AMP makes the stability analysis of the EMS compulsory. One possible approach is to apply the Routh–Hurwitz criterion [16] to the controlled FRF. This guarantees having all poles with negative real parts [17]. If we consider the FRF of a single-degree-of-freedom EMS defined in equation (26), the stability condition for the parallel configuration is found to be:

$$C_1 < C_{pi} \tag{27}$$

and for the series configuration:

$$C_2 > C_{pi}(1 + k_i^2) = C_{pi-1} \tag{28}$$

These conditions are obtained by considering in the FRF of equation (26) the expressions of ω_i^{oc} and ω_i^{sc} defined in table 1.

Nonetheless, when stability issues are faced, it is mandatory to model the whole system without neglecting any mode. Indeed, if the model of the EMS takes into account just some of the modes, spillover problems can occur. This means that the stability of the EMS must be studied starting from the complete model of equation (2a) together with equations (18) and (19) without applying the truncation to a single-degree-of-freedom system.

The stability conditions for the whole EMS are related to the strictest conditions among all the modes defined by equations (27) and (28). As for the parallel configuration, the strictest condition is the one related to the highest mode of the EMS:

$$C_1 < C_\infty \tag{29}$$

whereas, the strictest condition for the series layout is given by the lowest (i.e. the first) mode of the EMS:

$$C_2 > C_0 \tag{30}$$

These conditions are in accordance with those proposed by de Marneffe and Preumont [3]. Intuitively, the stability limits can also be related to the effects of the NC on the values of ω_i^{oc} and ω_i^{sc}. In the parallel configuration, if $C_1 \to C_\infty$, ω_i^{oc} of the highest mode tends to $+\infty$ (see table 1). Thus, the destabilisation process in this case comes from a high-frequency mode whose open-circuit frequency reaches $+\infty$. In contrast, for the series configuration, if $C_2 \to C_0$, ω_i^{sc} of the first mode tends to zero. Thus, the destabilisation comes from a low-frequency mode whose short-circuit frequency reaches 0.

2.7. Effect of negative capacitance

The MEMCF without any NC for mode i is k_i, defined by equation (12). When we consider a negative capacitance in parallel or series configuration, we have defined an enhanced coupling factor $\tilde{k}_i$, which is the coupling factor of the EMS viewed from the shunt impedance Z_{sh}, and thus including the negative capacitance. Table 1 shows the values of $\tilde{k}_i$ (see equation (23)), which are always higher than k_i if the stability conditions of section 2.6 are fulfilled. The main effect of the negative capacitance is to artificially[4] increase the MEMCF by changing the capacitance of the piezoelectric patch viewed from the shunt (the equivalent capacitance for series and parallel configurations, given by equations (20)). According to Thomas *et al* [2], the higher the MEMCF is, the better the vibration attenuation provided by the resistive shunt is. Thus, the addition of the NC allows the attenuation performance provided by the shunt control to be artificially improved.

The increase in the MEMCF can also be viewed as an increase in the distance between the open- and short-circuit eigenfrequencies (see table 1), as shown in figure 4. As for the parallel configuration, the short-circuit eigenfrequencies are not changed by the presence of the NC, whereas the open-circuit eigenfrequencies are shifted towards higher frequency values. Note that the closer C_1 is to the stability limit, the higher ω_i^{oc} and $\tilde{k}_i$ are. As for the series configuration, the open-circuit eigenfrequencies are not changed by the presence of the NC, but the short-circuit eigenfrequencies are shifted towards lower frequency values. The closer C_2 is to the stability limit, the lower ω_i^{sc} is and the higher $\tilde{k}_i$ is.

The addition of the NC makes it possible to increase the MEMCF by shifting either the open- or short-circuit eigenfrequency, depending on the way the NC is connected to the piezoelectric patch and the resistance R_{sh} (i.e. in parallel or series). The next section proposes a new shunt circuit layout with a couple of NCs and a resistance. The use of two NCs together allows both the open- and short-circuit eigenfrequencies to be shifted at the same time. Thus, the increase in the MEMCF is higher than that achievable by using parallel and series configurations. A detailed comparison of the enhancement of the MEMCF provided by the three configurations (i.e. series, parallel and the new one) will be given in the next section.

3. A new electrical circuit layout with negative capacitances

The previous sections showed that the use of an NC artificially increases the MEMCF. The idea behind the new circuit proposed herein is to increase the open-circuit eigenfrequencies and to decrease the short-circuit eigenfrequencies at the same time by using two NCs: one connected in parallel ($-C_1$) and the other in series ($-C_2$), as in evidence in figure 5.

---

4 We say artificially because the MEMCF is an intrinsic property of the EMS that depends on the piezoelectric material and on the geometry of the system.

Figure 5. The new proposed circuit with two NCs.

Therefore, this new configuration is named the series+parallel (SP) configuration.

3.1. Analytical model

Relying on figure 5 and following the same approach used in section 2.4, equation (2b) is replaced by:

$$\frac{(C_\infty - C_1)C_2}{(C_1 + C_2 - C_\infty)}V_{sh} - Q_{sh} + \sum_{i=1}^{N}\frac{\chi_i C_2}{C_1 + C_2 - C_\infty}q_i = 0. \tag{31}$$

If this model is restricted to the ith vibration mode ($q_n = 0 \ \forall n \neq i$), using the model proposed in equation (9) with the static correction, one defines the following equivalent capacitance:

$$C_{eqsp} = \frac{(C_{pi} - C_1)C_2}{C_1 + C_2 - C_{pi}}. \tag{32}$$

for the network made up by the three capacitances (C_{pi}, $-C_1$ and $-C_2$).

Then, using the change of variable of equation (21) with $C_{eq} = C_{eqsp}$, the model of equations (22a), (22b), (22c) is obtained again with the following short- and open-circuit eigenfrequencies:

$$\omega_i^{sc} = \sqrt{\omega_i^2 - \frac{\chi_i^2}{C_1 + C_2 - C_{pi}}} \tag{33}$$

$$\omega_i^{oc} = \sqrt{\omega_i^2 + \frac{\chi_i^2}{C_{pi} - C_1}} \tag{34}$$

and with $\tau_e = R_{sh}C_{eqsp}$.

As expected, the use of two NCs in the shunt circuit allows us to decrease the short-circuit eigenfrequencies and to increase the open-circuit ones at the same time, thus leading to an enhanced MEMCF $\tilde{k}$:
$$\tilde{k}_i = \frac{k_i}{\sqrt{\left(1 - \frac{C_1}{C_{pi}}\right)\left(1 + \frac{C_1}{C_2} - \frac{C_{pi}}{C_2}\right)}} \tag{35}$$

This is illustrated in figure 4.

The analytical formulation of the FRF of the SP configuration described here is exactly the same as that of the series and parallel configurations (and of the simple R-shunt, see section 2.4 and [2]), defined by equation (26), where the values of ω_i^{sc}, ω_i^{oc} and τ_e to be considered depend on the NC layout used. The parameters involved in the definition of H_i

Figure 6. The trend of the EMEMCF $\tilde{k}_i$, normalised by k_i ($\tilde{k}_i/k_i$), as a function of β, for the three NC configurations (parallel, series and series+parallel), with $\beta = \beta_\mathrm{p} = \beta_\mathrm{s} = \beta_{\mathrm{sp1}} = \beta_{\mathrm{sp2}}$. The grey region shows an example of the region for which the system is unstable, for β above 0.9 in this particular case.

are gathered in table 1 for the parallel, series and SP configurations.

3.2. Stability conditions for the ideal SP configuration

The stability condition for SP can be deduced by those of section 2.6 or, equivalently, by applying the Routh–Hurwitz criterion to the denominator of equation (26). The most restrictive conditions relating to the first and last modes (as explained in section 2.6) are:

$$C_1 < C_\infty \qquad \text{and} \qquad C_1 + C_2 > C_0 \qquad (36)$$

In this case we found two stability conditions to be satisfied at the same time. Indeed, the open-circuit eigenfrequency of the highest mode must not shift to $+\infty$ and the short-circuit eigenfrequency of the first mode must not reach the null frequency.

3.3. Effect on the MEMCF

The new circuit proposed herein is able to increase the MEMCF more than the series and parallel configurations, as explained in the previous sections. A straightforward approach to having a quantitative understanding of the benefits provided by the SP configuration is possible by considering a single-degree-of-freedom system. We define four indexes able to describe how much the negative capacitance, related to each possible configuration, is far from $C_{\mathrm{p}i}$: β_1 for the parallel, β_2 for the series, and β_{sp1} and β_{sp2} for the SP configuration. Their expressions are:

$$\beta_1 = \frac{C_1}{C_{\mathrm{p}i}}, \qquad \beta_2 = \frac{C_{\mathrm{p}i}}{C_2},$$
$$\beta_{\mathrm{sp1}} = \frac{C_1}{C_{\mathrm{p}i}}, \qquad \beta_{\mathrm{sp2}} = \frac{C_{\mathrm{p}i}}{C_1 + C_2} \qquad (37)$$

With these definitions, null β values correspond to a situation where no NCs are added to the circuit ($C_1 = 0$ and

$C_2 = +\infty$). In contrast, β coefficients equal to one mean that the values of the NCs are beyond but close to the instability condition.

Table 2 gathers the values of ω_i^{sc}, ω_i^{oc}, $\tilde{k}_i$ and τ_e as a function of β, obtained with those of table 1. Figure 6 shows $\tilde{k}_i/k_i$ (i.e. normalised enhanced coupling factor) as a function of β (achieved with the closed form expressions of the third row of table 2) and enables the benefit of the negative capacitance to be interpreted in terms of MEMCF enhancement. The two single capacitance configurations (series and parallel) give the same coupling factor enhancement for a given value of the β index. Moreover, for any value of β, the SP configuration always displays higher $\tilde{k}_i$ values than a single negative capacitance in series or in parallel.

Since $\tilde{k}_i$ tends to $+\infty$ when β approaches 1, one might think it possible to design a negative capacitance circuit with infinite performance. However, the performances are limited by the stability limit (see equations (36), (30) and (29)), which are discussed here as a function of the β indexes. The value of β, defined above, depends on $C_{\mathrm{p}i}$ and thus only on the ith mode considered in the corresponding 1 dof model. Actually, the value(s) of β for which the system becomes unstable depend on C_0 and C_∞ (see sections 2.6 and 3.2):

$$\beta_1^{\mathrm{inst}} = \beta_{\mathrm{sp1}}^{\mathrm{inst}} = \frac{C_\infty}{C_{\mathrm{p}i}}, \qquad \beta_2^{\mathrm{inst}} = \beta_{\mathrm{sp2}}^{\mathrm{inst}} = \frac{C_{\mathrm{p}i}}{C_0}, \qquad (38)$$

and thus depend on the complete N dof model and not only on the considered ith mode, as $C_{\mathrm{p}i}$ does. In practice, $C_0 > C_{\mathrm{p}i} > C_\infty$, depending on the considered mode, so that the stability limits in terms of β are smaller but close to one. We can notice from figure 2 that the β^{inst} coefficients for the series and parallel cases are different. Moreover, the closer $C_{\mathrm{p}i}$ is to C_∞ (parallel) or C_0 (series), the higher the stability threshold on the value of β is (i.e. the higher the value of β^{inst} is) and the the higher the attenuation performance is. Hence, the maximum achievable value of β for the two NC configurations depends on the mode considered. Two extreme cases are worth taking into account:

- according to equation (16), if the considered mode is in the low frequencies of the EMS spectrum, $C_{\mathrm{p}i}$ will be closer to C_0 than to C_∞, so that the stability limit for the series configuration ($C_2 > C_0 \simeq C_{\mathrm{p}i}$) will be reached for values of β_2 close to 1 ($\beta_2^{\mathrm{inst}} \simeq 1$), whereas the stability limit for the parallel configuration ($C_1 < C_\infty < C_{\mathrm{p}i}$) will be reached for values of β_1 far from 1 ($\beta_1^{\mathrm{inst}} < 1$). According to figure 6, in this case the series configuration will perform better than the parallel configuration;
- the opposite situation holds for high-frequency modes: the parallel configuration will theoretically perform better than the series one ($\beta_1^{\mathrm{inst}} \simeq 1$, $\beta_2^{\mathrm{inst}} < 1$).

To fix the ideas, we present an example considering an arbitrary EMS with 10 degrees of freedom. This example will allow us to explain clearly when it is convenient to use either the parallel or the series configuration, and when the SP becomes highly efficient if compared to these traditional NC layouts. In the example, the modes of the EMS are assumed to have the same MEMCF value, which is $k_i = 0.1$. The values

Table 3. Value of $C_{\mathrm{p}i}$ and stability limits in term of the β indexes and corresponding coupling factor enhancement $\tilde k_i/k_i$ for an arbitrary EMS with ten natural modes, with $k_i = 0.1$ for all the ten modes.

			Parallel config.		Series config.		SP config.
	$C_{\mathrm{p}i}/C_0$	$C_{\mathrm{p}i}/C_\infty$	β_1^{inst}	$\tilde k_i/k_i$	β_2^{inst}	$\tilde k_i/k_i$	$\tilde k_i/k_i$
mode 1	1/1.01	1.09	0.92	3.56	0.99	10	10.56
mode 5	1/1.05	1.05	0.95	4.47	0.95	4.47	6.24
mode 9	1/1.09	1.01	0.99	10	0.92	3.56	10.56

of $C_{\mathrm{p}i}$ (equation (14)), as compared to C_0 (equation (15)) and C_∞, are gathered in table 3 for the first, the fifth and the ninth mode. As for the first mode, the series configuration works better than the parallel one at the stability limit because the first mode is in the low frequency part of the spectrum. Indeed, the series configuration is able to increase the coupling factor by a factor of 10, whereas the parallel one allows us to achieve a value of EMEMCF just 3.56 times the original MEMCF. As for the ninth mode, located in the upper part of the frequency spectrum, the opposite result is observed. As for the fifth mode, the parallel and series configurations show the same performance: a coupling factor enhancement of a factor 4.47 is achieved by both the NC configurations. The performance of the SP configuration is also shown in table 3. Since its stability depends on two conditions, related to the two negative capacitances in series and in parallel, the best gain in using an SP configuration as compared to a single NC in parallel or series configuration is for the medium frequency modes: for mode 5, the SP configuration gives a coupling factor enhancement of 6.24 times instead of 4.47 (obtained with the traditional NC layouts).

4. Optimisation and performance with ideal circuits

Sections 2 and 3 described the mathematical model to treat EMSs shunted with impedances made up by NCs and R_{sh} as well as the effect of NCs on the MEMCF. This section is aimed at the derivation of the analytical procedures for defining the optimal values of the shunt impedance components (i.e. NC and R_{sh}) in order to achieve the best vibration

reduction, as well as for the quantification of the performance of the shunt in terms of vibration reduction.

4.1. Tuning of the negative capacitance

Section 3.3 showed that the closer the negative capacitances are to the stability limits, the higher the EMEMCF is. Therefore, the attenuation performance can be improved using negative capacitances as close as possible to the stability limits.

4.2. Tuning of the resistance R_{sh} for single mode control

The other component of the shunt circuit to be tuned is the resistance R_{sh}. This section explains how to optimise it when single mode vibration reduction is required. The criterion proposed herein is based on considerations of the shape of the controlled FRF of the EMS.

If the mechanical system to damp shows low modal density, we can approximate the response of the EMS as the one given by the ith mode. Therefore, it is possible to define the optimal value of R_{sh} by considering the FRF H_i of equation (26), which is valid for the R-shunt without the NC [2] as well as for the parallel, series and SP configuration, in the case of a 1 dof approximation of the model (see section 2.5). This means that the procedure used to find the optimal value of R_{sh} for a traditional R-shunt can be applied to the present cases with the negative capacitance. It will also provide results of the same form for the three layouts.

As suggested in [1, 2, 18, 19], the optimisation problem is solved by neglecting the structural damping ξ_i. Under such a hypothesis, there exists a point (here denoted by F) common to the amplitudes of all the FRFs of the EMS when R_{sh} is varied. Since F is common to all curves describing the

amplitude of the FRF, the optimum one (the one which has the lowest peak amplitude) is that with its maximum at point F. The frequency value ω_F associated with point F can be obtained by remarking that, among all possible FRFs, this point is common to two particular cases: the one in the short-circuit ($R_{\text{sh}} = 0$ and $\tau_e = 0$) and the one in the open-circuit ($R_{\text{sh}} = +\infty$ and $\tau_e = +\infty$), for which the FRF expression assumes a simple mathematical form. The frequency ω_F is found to be:

$$\omega_F = \sqrt{\frac{(\omega_i^{\text{oc}})^2 + (\omega_i^{\text{sc}})^2}{2}} \tag{39}$$

where ω_i^{oc} and ω_i^{sc} are calculated depending on the configuration used (i.e. series, parallel, SP; see table 1). The associated optimal value for τ_e is:

$$\tau_e^{\text{opt}} = \frac{1}{\omega_F} \tag{40}$$

The above reasoning is illustrated in figure 4, where the location of point F is shown with a bullet on the R, S, P and SP optimised curves (with $\tau_e = \tau_e^{\text{opt}}$), depending on the NC configuration considered. The above theoretical results are also validated since these optimised responses have their maximum at the crossing of the corresponding OC (i.e. $R_{\text{sh}} = +\infty$) and SC (i.e. $R_{\text{sh}} = 0$) curves.

The above parameters τ_e^{opt} and ω_F can be rewritten in terms of $\tilde{k}_i$ by noticing that $(\omega_i^{\text{oc}})^2 = \omega_i^2 \tilde{k}_i^2 + (\omega_i^{\text{sc}})^2$ (equation (23)) and by writing $(\omega_i^{\text{sc}})^2 = \omega_i^2 (1 - K^2)$, with K defined in table 4. One obtains:

$$\omega_F = \frac{1}{\tau_e^{\text{opt}}} = \omega_i \sqrt{\frac{\tilde{k}_i^2 + 2 - 2K^2}{2}}. \tag{41}$$

Finally, the optimal value of R_{sh} can be obtained by using the above equation together with the last row of tables 1 or 2.

### 4.3. Performance evaluation for single mode control

The performance of the shunts is evaluated by defining the vibration attenuation parameter A_{dB}, proposed in [2, 20] for passive shunts, as:

$$A_{\text{dB}} = 20 \log_{10} \frac{H_{\text{sc}}}{H_{\text{sh}}} \tag{42}$$

where H_{sc} is the FRF peak amplitude in short-circuit configuration without any shunt (i.e. uncontrolled EMS) and $H_{\text{sh}} = |H_i|_{\Omega = \omega_F, \tau_e = \tau_e^{\text{opt}}}$ is the FRF peak amplitude with the optimised shunt (with $\tau_e = \tau_e^{\text{opt}}$) connected. A_{dB} is shown in figure 7. Since $H_{\text{sc}} = 1 / (2 \xi_i \omega_i^2 \sqrt{1 - \xi_i^2})$, after some symbolic manipulations, one obtains a single expression of A_{dB} valid for all four shunt layouts studied in this paper:

$$A_{\text{dB}} = 20 \log_{10} \frac{\tilde{k}_i^2 + 2\sqrt{2} \xi_i \sqrt{2 + \tilde{k}_i^2 - 2K^2}}{4 \xi_i \sqrt{1 - \xi_i^2}} \tag{43}$$

where the enhanced coupling factor $\tilde{k}_i$ takes the values of the third rows of tables 1 and 2 depending on the configuration used. The values of K are gathered in table 4.
Figure 7. Attenuation A_{dB} achievable with the four shunt layouts as a function of the coupling factor k_i (for the R-shunt) and of the enhanced coupling factor $\tilde{k}_i$ for the shunts with NC (parallel, series and SP), for several values of structural damping ξ_i. For each value of ξ_i, four curves are merged, one for each configuration: parallel, series, SP and simple resistive shunt.

The first major result from equation (43) is that, for a negative capacitance shunt in parallel configuration, A_{dB} has the same form as the one for a standard R-shunt, provided k_i is replaced by the enhanced coupling factor $\tilde{k}_i$. As for the series and SP configuration, a slight difference is brought about by the term K^2. In these two latter situations, by noticing (tables 2 and 4) that K and $\tilde{k}_i$ are functions of k_i and β only, A_{dB} can be expressed as a function of $\tilde{k}_i$ and β_2 (or β_{sp2}) only. To evaluate the effect of K^2, figure 7 shows A_{dB} as a function of $\tilde{k}_i$ for several values of ξ_i. It shows that, for each value of ξ_i, all the curves are almost merged, so that in practice the effect of the term K^2 can be neglected: for a negative capacitance shunt, A_{dB} has the same form as the one for a standard R-shunt, provided k_i is replaced by the enhanced coupling factor $\tilde{k}_i$. This result is very interesting in practice since it enables us to estimate the performance of the negative shunts relying only on two simple graphs. Indeed, it is sufficient:

- to know the values of the MEMCF k_i and the damping factor ξ_i for the considered mode;
- to know the margin from the stability limit of the considered negative capacitance shunt (the value of β, see section 3.3). Then, figure 6 enables us to estimate the increase in the coupling factor, from k_i to $\tilde{k}_i$;
- then, figure 7 leads us to estimate the resonance attenuation brought about by the considered shunt as a function of $\tilde{k}_i$ and ξ_i.

In the same manner as for a standard R-shunt (see [2]), the higher the coupling factor k_i is and the lower the structural damping ξ_i is, the better the attenuation performances are.

Another way of evaluating the shunt performances is to consider the magnification factor at resonance D—that is the ratio between the resonance peak amplitude H_{sh} and the static (for $\Omega = 0$) amplitude of the FRF ($H_i(\Omega = 0) = 1/(\omega_i^{\text{sc}})^2$). Figure 8 shows D as a function of $\tilde{k}_i$. An interesting point is

Table 4. Definition of K.

R-shunt	Parallel	Series	SP
$K = 0$	$K = 0$	$K = \dfrac{\chi_i}{\omega_i \sqrt{C_2 - C_{pi}}} = k_i \sqrt{\dfrac{\beta_2}{1 - \beta_2}}$	$K = \dfrac{\chi_i}{\omega_i \sqrt{C_1 + C_2 - C_{pi}}} = k_i \sqrt{\dfrac{\beta_{sp2}}{1 - \beta_{sp2}}}$
Figure 8. The magnification factor at resonance D due to the four shunt layouts as a function of the coupling factor k_i (for the R-shunt) and of the enhanced coupling factor $\tilde{k}_i$ for the shunts with NC (parallel, series and SP), for several values of structural damping ξ_i. For each value of ξ_i, four curves are merged, one for each configuration: parallel, series, SP and simple resistive shunt.

that for low structural damping ξ_i and a high coupling factor, several D curves are merged, so that D only slightly depends on ξ_i (for instance, the curves for $\xi = 0.1\%$ and $\xi = 0.01\%$ are merged for $\tilde{k}_i > 0.2$). As a consequence, with large coupling factors achievable using NCs, the amplitude at resonance depends mainly on the coupling factor and no longer on the damping factor.

4.4. Tuning of the resistance R_{sh} and performance evaluation for multi-mode control

When multi-mode control is required, numerical minimisations can be carried out in order to find the value of R_{sh} which fulfills the desired goal (e.g. H_∞ control, H_2 control). This section explains how to find the value of R_{sh} without carrying out any numerical minimisation and thus avoiding any possible problems relating to minimisation procedures (e.g. local minima). This goal will be achieved by means of an easy-to-apply graphical approach relying on an analytical formulation, as explained underneath.

For a given value of R_{sh} (and thus of τ_e), we call ω_i^r the resonance frequency of mode i, i.e. the frequency for which the FRF modulus $|H_i|$ reaches its maximum. We have $\omega_i^{sc} < \omega_i^r < \omega_i^{oc}$ when τ_e is varied. This resonance frequency ω_i^r can be calculated by solving the following equation as a function of Ω:

$$\frac{\partial |H_i(\Omega)|^2}{\partial \Omega} = 0 \tag{44}$$

Once $\omega_i^r(\tau_e, \omega_i)$ is known as a function of τ_e, the amplitude at the resonance can be derived with equation (26):

$$H_i^{max} = |H_i(\Omega = \omega_i^r)|. \tag{45}$$

It must be noted that the performance indicator A_{dB} (equation (42)) is related to the value of H_i^{max} for $\tau_e = \tau_e^{opt}$ since $H_{sh} = H_i^{max}|_{\tau_e = \tau_e^{opt}}$.

To calculate ω_i^r, equation (44) gives (if ξ_i is considered null, as done when calculating ω_F) the following seventh order equation in Ω:

$$\Omega(a\Omega^6 + b\Omega^4 + c\Omega^2 + d) = 0 \tag{46}$$

where

$$a = 2\tau_e^4, \quad b = 4\tau_e^2 - 2(\omega_i^{oc})^2\tau_e^4,$$
$$c = 2 - 4(\omega_i^{oc})^2\tau_e^2, \quad d = (\omega_i^{oc})^4\tau_e^2 - (\omega_i^{sc})^4\tau_e^2 - 2(\omega_i^{sc})^2 \tag{47}$$

The terms ω_i^{sc} and ω_i^{oc} must be calculated according to the configuration used (see table 1).

Equation (46) leads to the trivial solution $\Omega = 0$ and to three other possible solutions for Ω^2. The third order equation in Ω^2 can be solved analytically by using the formula found by Tartaglia [21]. Let us define:

$$p = c/a - b^2/(3a^2), \quad m = d/a - bc/(3a^2)$$
$$+ 2b^3/(27a^3), \quad \Delta = m^2/4 + p^3/27 \tag{48}$$

If $\Delta < 0$, the solutions of the cubic equation in Ω^2 (see equation 46) are:

$$\Omega_1^2 = 2\sqrt{-p/3}\cos[\vartheta/3] - b/(3a) \tag{49a}$$

$$\Omega_2^2 = 2\sqrt{-p/3}\cos[(\vartheta + 2\pi)/3] - b/(3a) \tag{49b}$$

$$\Omega_3^2 = 2\sqrt{-p/3}\cos[(\vartheta + 4\pi)/3] - b/(3a) \tag{49c}$$

where $\vartheta = \arctan[\sqrt{-\Delta}/(-m/2)]$ and arctan must be intended as the four-quadrant arctangent. If $\Delta \geqslant 0$, the solutions are not provided here because when Δ is higher than or equal to zero, the attenuation provided by the shunt is usually so high that the resonance is canceled by the control action. As a result, the maximum of $|H_i|$ between ω_i^{sc} and ω_i^{oc} is lower than its static component (i.e. $|H_i(\Omega = 0)| = 1/(\omega_i^{sc})^2$), and the only physical solution provided by equation (46) is $\omega_i^r = 0$[5]. Therefore, if the

---

[5] This result was checked by means of simulations with $2\pi 10 \text{ rad/s} < \omega_i < 2\pi 3000 \text{ rad/s}$, $0.001 < k_i < 0.3$, $0 < \beta < 1$ and $\tau_e^{opt}/100 < \tau_e < 100\tau_e^{opt}$. We chose the simulation values in order to cover most of the engineering applications.
Figure 9. The trend of v_i^{max} and A_{RMS} for the four modes of the EMS described in table 5 for an NC in series configuration. $C_{pi} = 30.5$ nF and $C_2 = 36.6$ nF. The values of the mode shape components used here are: $\Phi(x_f) = [1.7167, 0.2450, 0.8020, 1.1987]'$ and $\Phi(x_m) = [2.3452, 2.2935, -2.8761, -2.2822]'$.

Table 5. Modal data of the system used for the numerical simulations and for the experimental tests.

Mode number	$\omega_i/(2\pi)$ [Hz]	ξ_i	k_i
1	39.72	0.0045	0.2716
2	187.34	0.0030	0.1037
3	509.00	0.0026	0.0710
4	986.42	0.0028	0.1222

chosen value of τ_e gives a value of Δ higher than or equal to zero, the maximum of the amplitude of H_i can be approximated by its static component. If the chosen value of τ_e gives a value of Δ lower than zero, the three solutions (49a)–(c) must be taken into consideration. Only one of them has a physical meaning and it is found to be (49a).[5] If a different situation with respect to the cases considered in footnote 5 is taken into account, and equation (49a) does not provide a physical solution, solutions (49b) and (49c) must be considered, because one of them will provide the correct one.

Therefore, the curves relating the value of R_{sh} to H_i^{max} can be drawn for all the modes to be controlled. This gives us the possibility of finding out the optimal value of R_{sh} for a given control problem with a graphical approach, as explained in the following example. Let us consider the system described in table 5 (similar to that used for experimental tests in the following), an NC in series and a H_∞ control problem on the velocity of a given point of the EMS. If x_m is a point where the structural response is measured and x_f is a point where an excitation force is provided, the FRF between this force and the displacement of the structure in x_m is obtained by multiplying equation (26) by $\Phi_i(x_m)\Phi_i(x_f)$. Hence, for each of the modes considered it is possible to draw the curve relating R_{sh} to the maximum of the velocity FRF:

$$v_i^{\text{max}} = |\Phi_i(x_f)\Phi_i(x_m)\omega_i^{\text{r}} H_i^{\text{max}}| \tag{50}$$

The resulting curves are plotted in figure 9. In this figure, the graph has τ_e on the x-axis in place of R_{sh} because C_{pi} was fixed to the same value for all four modes (indeed the values of C_{p1} to C_{p4} were so close that an average value has been used) and thus a given value of R_{sh} corresponds to the same value of τ_e for all the modes. The portions of the solid curves with an increased width (blue and orange in figure 9) are those providing evidence of the highest peak of the velocity FRF for the EMS as a function of τ_e. The minimum of this line corresponds to the value of R_{sh} to be chosen if an H_∞ control must be performed. This figure clearly shows the optimal value of τ_e without the need to carry out numerical minimisations, and evidence of this optimal value is provided by a star in the figure. The same procedure can be applied to acceleration as well, just by multiplying equation (50) by ω_i^{r}.

This graphical approach can also lead us to find the optimal value of R_{sh} for other control problems. As an example, for an H_2 control in velocity (i.e. minimisation of the velocity root mean square value, RMS), one can consider minimising the following approximated quantity:

$$A_{\text{RMS}} = \sqrt{\sum_{i=1}^{N} \frac{(v_i^{\text{max}})^2}{2}} \tag{51}$$

The minimum of this curve (solid green curve in figure 9), highlighted by a triangle in figure 9, shows which value of τ_e makes the RMS minimum. Note that the H_∞ control (star) and the H_2 control (triangle) require different solutions, which can easily be found graphically, and the optimal values of τ_e for the H_2 and H_∞ problems do not correspond to the optimal values of the four modes (minima of the solid thin lines of figure 9).

This graphical approach works with FRFs, but it even allows us to solve problems where the input disturbance is not white random noise. Indeed, if the power-spectrum G_{dd} of the disturbance can be estimated, the control problem can be expressed not in terms of FRF but in terms of power-spectrum of the EMS response G_{rr}, which can be calculated in case of low modal density as:

$$G_{rr}(\omega_i^{\text{r}}) = G_{dd}(\omega_i^{\text{r}})|\Phi_i(x_m)\Phi_i(x_f)H_i(\omega_i^{\text{r}})|^2 \tag{52}$$

5. Real circuits

5.1. Negative capacitance layouts

Section 1 mentioned that an NC can be built using OP-AMPs and that we distinguish two different types: ideal circuits (ICs), which can be modelled as pure NCs, and more complicated circuits (real circuits, RCs), which cannot be modelled as pure negative capacitances. RCs are often used in practice because they offer significant advantages when compared to ICs. Indeed, they are able to overcome some of the main issues relating to ICs. All the circuits are discussed in this section.

A negative impedance can be built in practice by using an OP-AMP along with three different impedances
Figure 10. A negative impedance built by means of an OP-AMP (a) and its electrical model (b).

(i.e. Z_1, Z_2, Z_3), as shown in figure 10. The impedance of this circuit (the ratio between voltage and current intensity $\underline{V}/\underline{I}$) is:

$$Z_{\text{nc}} = \frac{-Z_1 Z_3}{Z_2} \tag{53}$$

Equation (53) is valid as long as the OP-AMP is considered ideal, which in turn means that the voltage difference between the inputs is null and no current flows in the inputs [15]. Z_{nc} becomes an NC if Z_1, Z_2 and Z_3 are replaced by resistances and a capacitance respectively. In order to obtain a pure negative capacitance—as in figure 3(c)—two different configurations are possible, labelled type A and type B circuits, as shown in figures 11(a), (b). In this case, we have an equivalent negative capacitance $-C_n$ with:

$$C_{\text{n}} = \frac{R_2 \hat{C}}{R_1} \tag{54}$$

and the corresponding circuits are denoted as ideal circuits (ICs).

Furthermore, some authors suggest adding a resistance $\hat{R}$ in parallel to the capacitance $\hat{C}$ [22], leading to the circuits of figures 11(c) and (d) (types AR and BR). These circuits, denoted as real circuits (RCs) in the following, are not pure NCs: their impedance Z_{nc} is equivalent to a pure NC, $-C_{\text{n}}$, (see equation (54)) in parallel with a negative resistance, $-\tilde{R}$, with:

$$\tilde{R} = \frac{R_1 \hat{R}}{R_2} \tag{55}$$

The parallel between $\hat{C}$ and $\hat{R}$ constitutes an undesired but necessary high-pass filter useful for solving practical problems such as bias-current and offset-voltage induced errors [22].

The addition of $\hat{R}$ is often necessary when a series configuration is taken into consideration. Instead, in the parallel configuration, the parallel between the capacitance of the piezoelectric actuator and R_{sh} (see section 5.2) already constitutes a high-pass filter. Nonetheless, the addition of $\hat{R}$ can be useful even in this case (as found in the experiments related to this paper) because the values of the capacitance of the piezoelectric actuator and R_{sh} can be unsuitable for properly stopping the low-frequency components. In such cases, it is useful to add $\hat{R}$ in order to produce a further parallel between $\hat{C}$ and $\hat{R}$ and thus a more efficient high-pass filter. Moreover, the polarity of the OP-AMP is of practical

importance (it has no influence in theory since equation (53) is the same whatever the $+/-$ input pin wiring be). As for a parallel configuration, the circuits of figure 11 can be used. For a series connection, the OP-AMP $+/-$ input pins must be inverted. Most of the circuits presented here and used to build an NC are employed in the literature, without providing any comparison between the different solutions. Table 6 shows how different authors have used different layouts.

The theoretical analyses carried out so far, in sections 2, 3 and 4, regard ICs without $\hat{R}$. The effect of adding $\hat{R}$ to the circuit on the behaviour of the shunt is now addressed.

5.2. Parallel configuration for real circuits

An RC in parallel configuration can be modelled as shown in figure 12(a). The total resistance in parallel to the piezoelectric actuator is the parallel between R_{sh} and $-\tilde{R}$ (due to the presence of $\hat{R}$, see equation (55)), which is named R_{p}:

$$R_{\text{p}} = \frac{-\tilde{R} R_{\text{sh}}}{R_{\text{sh}} - \tilde{R}} \tag{56}$$

This total resistance R_{p} can be considered as the new shunt resistance, and thus the analytical treatment is the same as the ICs in a parallel configuration with just one difference: the resistance R_{sh} must be replaced by R_{p} in the equations of sections 2, 3 and 4. Hence, the RCs in the parallel configuration can be fully described by the model presented so far. Therefore, the stability of the EMS is guaranteed if the condition of equation (29) is fulfilled and $R_{\text{p}} \geqslant 0$, and the tuning and performance of the shunt are those predicted in section 4.

5.3. Series configuration for real circuits

An RC in a series configuration can be modelled as shown in figure 12(b). The impedance Z_{rs} of the circuit composed by $-C_2$, $-\tilde{R}$ and R_{sh} in the Fourier domain is:

$$Z_{\text{rs}} = R_{\text{sh}} - \frac{\tilde{R}}{1 + j\Omega \tilde{R} C_2} \tag{57}$$

where the values of C_2 and $\tilde{R}$ depend upon the values of R_1, R_2, $\hat{C}$ and $\hat{R}$ (see equations (54) and (55)). Generally speaking, this circuit cannot be treated with the formalism of sections 2, 3.3 and 4. Nevertheless, there are some cases where the effect of $\tilde{R}$ can be neglected, depending on the frequency band of interest, as shown in sections 5.3.1 and 5.3.2.

5.3.1. Similar behaviour of RCs and ICs.
If $\hat{R}$—and thus $\tilde{R}$—tend to $+\infty$, the impedance Z_{rs} tends to that of an IC that writes:

$$Z_{\text{is}} = R_{\text{sh}} - \frac{1}{j\Omega C_2} \tag{58}$$

In the high frequency range $\Omega \gg 1/(\tilde{R} C_2)$, the effect of $\hat{R}$ can be neglected since $Z_{\text{rs}} \simeq Z_{\text{is}}$ (see figure 13) and the behaviour of the real circuit is the one of a pure negative capacitance (in series with R_{sh}). As a consequence, if all the controlled modes
Figure 11. Practical circuits to build a negative capacitance: type A (a), type B (b), type AR (c) and type BR (d) circuits in parallel configuration. For the series configuration, the pins of the OP-AMP must be exchanged.

Table 6. The NC layouts used in the literature, defined in figure 11. All series configurations have the OP-AMP $+/-$ input pins exchanged with respect to figure 11.

of the EMS have their natural frequency above $1/(\tilde{R}C_2)$, it is possible to use the results of sections 2, 3.3 and 4 without paying attention to $\hat{R}$.

It is possible to use the analytical formulation derived for ICs in a further case, even if the frequency range considered is below $1/(\tilde{R}C_2)$. This is the case in which the value chosen for R_{sh} is high. In this case the values of τ_e^{opt}, ω_i^r and A_{dB} obtained with Z_{rs} and Z_{is} are usually very close. Such similar results for Z_{rs} and Z_{is} are shown in section 6.2 (see figure 17 in particular). The different behaviour between Z_{rs} and Z_{is} becomes evident when R_{sh} is low, and in this case significant differences in the attenuation performance on the modes at low frequency become clear. Again, such a fact is shown in section 6.2. It is noticed that low values of R_{sh} mean that the control action is focused on the modes at high frequency.

5.3.2. Use of a compensation resistance. If the EMS shows natural frequencies to be controlled at low frequencies, below $1/(\tilde{R}C_2)$, and if the value of R_{sh} we use is low, the analytical treatment used for ICs is not reliable for RCs. The IC and RC series circuits only differ for the presence of $-\tilde{R}$, which degrades the shunt performances. The effect of $-\tilde{R}$ can be cancelled by adding a further passive resistance R_s in parallel to $-\tilde{R}$ and $-C_2$, as shown in figure 12(c). The parallel between R_s and $-\tilde{R}$ (which is physically obtained by placing R_s between the upper connector of the impedances in figures 11(c), (d) and the ground) gives an equivalent resistance R_{eq}, defined as:

$$R_{eq} = \frac{-\tilde{R}R_s}{R_s - \tilde{R}} \qquad (59)$$

The aim is to achieve high negative values of R_{eq} in order to cancel out the effect of $\tilde{R}$. Consequently, the required values of R_s should be close to $\tilde{R}$ ($R_s \simeq \tilde{R}$), which produce high negative values of R_{eq} ($|R_{eq}| \to +\infty$) and thus cancel out the effect of $\hat{R}$. In such a case, all the results of sections 2, 3.3 and 4 are valid and it is not necessary to consider $\hat{R}$. If the use of the compensation resistance R_s must be avoided for any practical reason (see section 6.2), a new analytical treatment can be developed for the shunt circuit in figure 12(b) (i.e. composed of $-C_2$, $-\tilde{R}$ and R_{sh}). This analytical treatment is given in appendix A.

*5.4. SP configuration for real circuits*

The SP circuit has been treated in section 3 and it is possible to deduce that this new configuration can be seen as an NC in
Figure 12. The equivalent model of the RC circuit for the parallel configuration (a); equivalent model of the RC circuit for the series configuration (b) and the addition of R_s (c).
Figure 13. Magnitude and phase of the impedance Z_{rs} for different values of $\hat{R}$. In this figure: $R_1 = R_2 = 5$ kΩ, $R_{sh} = 50$ kΩ and $\hat{C} = 40$ nF. The case with $\hat{R} = +\infty$ corresponds to an IC (i.e. Z_{is}).

**Figure 14.** Electronic circuit used for the SP configuration.

series with a piezoelectric patch with a decreased capacitance (i.e. $C_{eqp} = C_{pi} - C_1$, see figure 5 and equation (20)) as well as an enhanced MEMCF (i.e. $\tilde{k}_i = k_i / \sqrt{1 - C_1/C_{pi}}$, see table 1). Hence, the description of the SP layout with RCs can be derived from sections 5.3 and 5.2. In this work, the RC SP circuit (see figure 14) is built using the IC configuration for C_1 (i.e. the parallel NC) and an RC for C_2 (i.e. the series NC).

6. Experiments

The analytical results shown previously were validated by a series of experiments. The test set-up was a stainless steel cantilever beam (with a length of 178.8 mm, a width of 30.5 mm and a thickness of 1.1 mm) with two PIC 151 piezoelectric patches (with a length of 70 mm each, 0.5 mm thick and with wrapped electrodes) bonded as depicted in figure 15. The modes considered for the tests were the first four bending modes, whose characteristics are given in table 5 (the shapes of these modes are the usual ones for cantilever beams). The values of ω_i and ξ_i were estimated by means of experimental modal analysis and the values of k_i were estimated by deriving the ω_i and $\hat{\omega}_i$ values from the measured FRFs of the EMS in a short- and open-circuit and using equation (13). Note that the values of table 5 are just indicative values. Indeed, the tests described from here on were carried out over several months. Therefore, small changes to the modal data were faced each time (e.g. due to thermal shift) and as a result, all the modal data were estimated before each test session. The values of the modal parameters relating to each kind of test discussed further on in the paper will always be given explicitly. The cantilever beam was excited by a
Figure 15. Experimental set-up. Dimensions are in millimetres.
Figure 16. Experimental capacitance $C(\Omega)$ as a function of frequency of the piezoelectric patches in series.

contactless electro-magnetic actuator described in [23] composed by a fixed coil and a magnet bonded to the beam close to its tip (see figure 15). The vibrational response of the beam was measured by a laser Doppler velocimeter (Polytec PSV 400). The reference signal for the FRF computation was the intensity of the current that flowed in the coil, measured by a current clamp (Tektronix A622), assumed to be proportional to the electromagnetic force imposed on the magnet. A Brüel

& Kjaer 2712 power amplifier was used to feed the coil. The NCs were built as proposed in figure 11 using Texas Instruments OPA445 operational amplifiers [24], with some of the resistances built using potentiometers for easy tuning. The chosen design of the circuits will be made clear in the following.

6.1. Piezoelectric patch capacitance

The two piezoelectric patches were electrically linked in series. The equivalent capacitance $C(\Omega)$ of both patches in series was measured as a function of frequency with a network analyser (NA). The voltage signal generated by the NA was sent to the terminals of the piezoelectric patches in series with a resistance $R = 120\,\mathrm{k}\Omega$, and the current intensity in the circuit was measured by monitoring the voltage at the terminals of R, thus obtaining the impedance Z_p of the piezoelectric patches with the NA. The equivalent capacitance was then obtained by $C(\Omega) = 1/(j\Omega Z_p)$, as shown in figure 16. The trend of $C(\Omega)$ is in full agreement with the theoretical one (shown in figure 2). Since it was not possible to obtain the limit response in the low-frequency range with this method, the plot has been deleted under 20 Hz.

Estimating the values of C_0, C_∞ and C_{pi} for $i = 1, \dots 4$ is not straightforward, since (i) C_0 and C_∞ are the limits of $C(\Omega)$ in zero and high frequencies, which are not measured (ii) C_{pi} is the value of $C(\Omega)$ at an unknown frequency Ω between ω_i and ω_{i+1} (see section 2.2). A correct way of estimating C_0, C_∞ and C_{pi} would be to update the theoretical model of equation (4) until its response matches the experimental one of figure 16. This has not been done in the present study.

Here, $C(\Omega)$ was measured at a number of frequency values between the first and the fifth mode of the structure with a digital multimeter. The results were close to one another: between 31.1 and 30.0 nF, which is in agreement with the values shown in figure 16. Since these values are very close each other, we decided to use a sort of average value for all the modes: $C_{pi} \simeq C_p = 30.5$ nF for all of them ($i = 1, 2, 3, 4$), denoted by C_p in the following. C_0 was estimated by measuring the value of C_{p1} at 100 Hz with a digital multimeter and then calculating $C_0 = C_{p1}(1 + k_1^2)$. The result for C_0 was about 33.26 nF. C_∞ was estimated measuring the capacitance value at 100 kHz and the result was about 25.9 nF.

6.2. Tests with the compensation resistance

This section shows that the use of a compensation resistance R_s allows Z_{rs} (i.e. RC in series, see figure 12(b)) to be made similar to Z_{is} (i.e. IC in series) (see section 5.3). Different experiments were carried out with different configurations of the electrical parameters. Only one of them (employing type AR of figure 11) is taken into account here because all of the tests gave similar results. The values of the various parameters used for the experiment considered here are shown in table 7 (test 1 column). The value of R_s was changed step by step from $+\infty$ (i.e. the absence of R_s) up to values which made R_{eq} closer and closer to $-\infty$ ($R_s \simeq \tilde{R}$, see

Table 7. Values of parameters for the different tests presented in the paper.

equation (59)) in order to verify if an increased value of $|R_\text{eq}|$ was actually able to bring the behaviour of Z_rs closer and closer to that of Z_is. Figure 17 shows the relation between τ_e (see equation (25)) and $H_\text{sc}/H_1^\text{max}$ (it takes the value of A_dB if $\tau_e = \tau_e^\text{opt}$, see equations (42) and (45)) for the IC (i.e. $R_\text{eq} = -\infty$) and with some other values of R_eq for the first mode of table 7. The markers are related to the experimental results. The figure shows that a proper choice of R_s is actually able to make Z_rs similar to Z_is and that RCs tend to behave like ICs when $|R_\text{eq}|$ is increased.

Figure 17 also shows that all the curves of the plot are close to the blue solid curve, which represents the behaviour of the IC, when τ_e is high (over about $3.5 \cdot 10^{-3}$ s). Therefore, this means that RCs and ICs provide similar attenuation values when R_sh and τ_e are high, as already mentioned in section 5.3. Hence, RCs in this area can be well described by the approach presented for ICs, even if R_s is not used. Conversely, the addition of R_s is useful when R_sh is low. Indeed,

when R_sh is low, the distance between the curve related to the IC (solid blue curve) and the curves related to the RC (e.g. red dashed curve) increases with decreasing the value of $|R_\text{eq}|$, thus providing evidence of the different behaviour between RCs and IC (see the left-hand part of figure 17).

Some further facts are worth mentioning. There are two ways of letting the RC behave as an IC: add a compensation resistance R_s to bring the equivalent resistance R_eq to $-\infty$ (see equation (59) and figure 12(c)), or use high values of $\hat{R}$ (see equation (55)). The latter solution proves to be unfeasible. Indeed, $\hat{R}$ is needed to let the bias currents in the OP-AMP flow to the ground and its value cannot be increased too much. Values of $\hat{R}$ higher than 3 MΩ generated in the tests bias currents leading the OP-AMP output to saturation. Therefore, the addition of the compensation resistance R_s was necessary. Nevertheless, the addition of R_s can cause a problem as well: high values of the equivalent resistance $|R_\text{eq}|$
Figure 17. The trend of H_{sc}/H_1^{max} as a function of τ_e for the first mode of the experimental set-up for different values of R_{eq}. The lines are obtained by means of the analytical model, the circles are the experimental points relating to the case of $R_{eq} = -11.5$ MΩ ($R_s = 1.00$ MΩ), the triangles to the case of $R_{eq} = -1.86$ MΩ ($R_s = 1.82$ MΩ) and the squares to the case of $R_{eq} = -0.92$ MΩ (which is the case without using R_s). Refer to table 7 (test 1 column) for the value of $\bar{R}$.

(achieved using R_s) can lead to a significant DC voltage offset in the OP-AMP output. This phenomenon reduces the maximum possible dynamic output of the OP-AMP before saturation. Nonetheless, in the experiments carried out, if a value of $|R_{eq}|$ lower than about 100 MΩ was used, this offset often resulted equal to one or few volts.

Furthermore, the use of the compensation resistance R_s is needed when R_{sh} is low (see previously in this section) and the attenuation provided by the shunt circuit is focused at high frequency. In such cases, if R_s is not used, the lowest eigenfrequencies tend to be amplified because of the presence of $\hat{R}$. This makes the output of the OP-AMP oscillate at low frequency with large amplitudes, thus reducing the maximum possible dynamic output of the OP-AMP usable for vibration attenuation before saturation. Hence, both the situations (i.e. the use or the avoidance of R_s) lead to a decrease in the maximum possible dynamic output of the OP-AMP usable for vibration attenuation. Often, the DC offset due to R_s is lower than the amplitude of the low-frequency oscillations and thus the introduction of the compensation resistance R_s is advantageous.

Another reason for adding the compensation resistance R_s, despite the DC offset issue, is that the stability limits are improved with respect to the case of the RCs because they approach those of the ICs as $|R_{eq}|$ tends to ∞. Indeed, the stability limits for RCs are more restrictive than for ICs (see appendix A).

Figure 17 also shows that the analytical model presented in A, developed for RCs, is reliable and accurate. Indeed, the experimental points are very close to the numerical model (i.e. curves with finite values of the equivalent resistance R_{eq}). The accuracy of this model will be further remarked upon in section 6.3.

6.3. Validation of strategies for vibration reduction

This subsection aims at validating the single-mode and multimode optimisation strategies (section 4) and the stability limits (section 2.6) for the parallel and series configurations.

The parallel configuration was built using both an IC and an RC for the negative capacitance. Both the layouts proved to be reliable. Indeed, if an IC is used, R_{sh}—together with the piezoelectric patch capacitance—acts as a high-pass filter allowing the bias currents to flow to the ground. Hence, only IC will be discussed here. Furthermore, both type A and type B layouts were tested (see figure 11). Layout B proved to be more reliable so that all the tests shown further on in the section refer to such a configuration.

As for the series configuration, the IC (both type A and B) configurations led to the saturation of the OP-AMP and thus to instability because of the DC output component and bias currents. Therefore, the circuits tested in these experiments were built with an RC both with and without the addition of the compensation resistance R_s (see section 6.2). Both type AR and type BR layouts were tested. No significant differences were noticed in the behaviour of the two circuits. Therefore, the tests shown further on in this section refer only to type AR. Note that no further analyses were carried out for the differences between types A and B and between types AR and BR, because this was out of the scope of the paper and is related to a deeper analysis of electronic issues.

The single-mode optimisation presented in section 4 was validated for all of the first four bending modes, whose parameters are shown in table 7 (test 2 column). Different cases were considered by changing the NC value. We took into account the values of the NC both close to and far from the stability limits (i.e. $C_0 = 33.26$ nF for the series and $C_\infty = 25.9$ nF for the parallel, see section 6.1). The optimal value of R_{sh} for a given mode was calculated for each configuration by using equations (25) and (40) and the FRF was measured. Then, A_{dB} was calculated with the peak amplitude at the targeted resonance, with equation (42). Figure 18 shows the value of A_{dB} as a function of C_n/C_p (C_1/C_p for the parallel configuration; C_2/C_p for the series configuration; $C_p = 30.5$ nF), for the first four bending modes, and enables us to compare the experimental results with the theory predicted by equation (43) (solid lines in figure 18). There is a good agreement between the theory and experiments. The only case in which the accuracy decreases is related to the control of the second mode with the NC in series (i.e. discrepancies between the experiments and analytical expectations of 2 dB on average, see figure 18(b)); however, in this case the signal-to-noise ratio of the structural response signal was found to be poor.

As for the validation of the stability limits, it is worth highlighting some facts. The instability limits found in section 2.6 and appendix A are related to the dynamic instability of the EMS (i.e. the classical instability due to poles with positive real parts), which were derived considering the OP-AMP as ideal. In practice, another kind of instability can arise which is related to the non-linear behaviour of the OP-AMP. Indeed, when the voltage induced at the terminal of the NC is high, the output of the OP-AMP can saturate, leading to the instability of the EMS. The closer C_n is to the stability limit, the higher the voltage induced at the terminal of the NC is, and thus such a problem arises when the value of C_n/C_p approaches 1. Therefore, it is important to
Figure 18. The trend of A_{dB} as a function of C_n/C_p for the first mode (a), second mode (b), third mode (c) and fourth mode (d) of the piezoelectric beam. The lines are obtained by means of the analytical model, the circles are the experimental points. The vertical dashed lines correspond to the stability limits (i.e. C_∞ for the line on the left and C_0 for the line on the right). The curves and circles on the left of $C_n/C_p = 1$ are related to the parallel configuration and the curves and points on the right of $C_n/C_p = 1$ are related to the series layout. For the experiments relating to test 2 of table 7, the series configuration was built using R_s (see section 6.2).

distinguish between these two cases (i.e. dynamic instability and OP-AMP saturation) to validate the stability limits of section 2.6.

As for the parallel configuration, the dynamic instability was found for a value of C_1 equal to 22.9 nF (which corresponds to $\beta_1 = C_1/C_p = 0.75$), which is lower than the theoretical limit (i.e. 25.9 nF, $\beta_1^{inst} = C_\infty/C_p = 0.85$). Nonetheless, it is hard to have a very accurate estimation of C_∞ (see section 6.1 and [25]) and the value of the capacitance measured at 100 kHz is just an estimation. Furthermore, the modes which become unstable with the parallel configuration are those at high frequency (section 2.6), where the model can start to become less accurate. For all these reasons, the experimental limit (i.e. 22.9 nF) can be considered as a satisfactory validation of the condition given in section 2.6. The experimental value of C_1/C_p closest to the stability limits shown in figure 18 is 0.65, because instability phenomena due to saturation of the OP-AMP sometimes occurred for values of C_1/C_p between 0.65 and 0.75.

As for the series configuration, dynamic instability did not occur until values of $\beta_2 = C_p/C_2$ lower than 0.88. This result is in good agreement with the theoretical expectation for the stability limit: $\beta_2^{inst} = 0.917$ (see equation (38)). The test with $\beta_2 = 0.88$ was not included in figure 18 because it

was performed just for the first mode (for this test the experimental value of A_{dB} was found to be 1.5 dB lower than the theoretical expectation). We could not perform the same tests for modes 2 to 4 because the low value of R_{sh} required for optimal control, together with this C_2/C_p value, led to a significant non-linear behaviour of the OP-AMP and the piezoelectric patch.

Finally, figure 19 shows the experimental validation of the curves of H_i^{max} as a function of τ_e (i.e. equations (45) and (49a)) used for the graphical multi-modal optimisation strategy presented in section 4.4. The parallel NC for this test was built as mentioned at the beginning of this section (i.e. type B), while the series NC was built as in section 6.2 but without adding the compensation resistance R_s. This choice allowed the authors to further validate the model for RCs presented in appendix A. The parameter values used in the tests are provided in table 7 (test 3 column for the parallel and test 4 column for the series). Again, the agreement between numerical expectations and experimental results is excellent.

The curves of figure 19 give us the occasion to show that the refined model for the piezoelectric patch capacitance, introduced in equations (8) and (9), allows us to better estimate the performance of the control action. Indeed, figure 20 shows the comparison between the curves describing
Figure 19. The trend of H_{sc}/H_i^{max} as a function of τ_e for the parallel (a) and series (b) configurations, for the four modes of the experimental set-up. The lines are related to the analytical model (section 4.4) and the markers to experiments ('○': mode 1; '□': mode 2; '◇': mode 3; '△': mode 4). See test 3 of table 7 for the parallel configuration and test 4 for the series configuration. The series configuration was built without using R_s (see appendix A).

Figure 20. The trend of H_{sc}/H_i^{max} as a function of τ_e for the parallel configuration, for the four modes of the experimental set-up. The solid lines are related to the analytical model using C_{pi} (equations (8) and (9)), the dashed lines to the analytical model using C_∞ (equation (6)), and the markers to experiments ('○': mode 1; '□': mode 2; '◇': mode 3; '△': mode 4).

H_{sc}/H_i^{max} achieved using the refined model (solid lines in the figure) and the ones using C_∞ (dashed lines) for the parallel case. The solid lines and the experimental points in figure 20 are the same lines and points of figure 19(a). The estimations provided by the refined model proved to be much more accurate.

6.4. Tests with the SP configuration

This subsection aims at testing the newly proposed SP configuration and comparing its attenuation performances with

Figure 21. Experimental FRFs (displacement U to force F_{ext} ratio), around the first resonance of the EMS, for different configurations, analogous to figure 4 (except for the short circuit response of the SP configuration (SCSP) that is slightly distinct to SCS in experiments).
Figure 22. FRFs (displacement U to force F_{ext} ratio), around the first resonance of the EMS, for different configurations, analogous to figure 4. Comparison of experiments (solid lines) and theory (dashed lines).

those of traditional circuits. In particular, the SP layout was compared to a simple resistive shunt (i.e. no use of any NC), the series configuration of the NC and the parallel layout of the NC. As for the SP circuit, the NC in parallel was built using an IC (layout B), while the NC in series was built with an RC (layout AR) with the addition of the compensation resistance R_s (see section 6.2). The circuit is displayed in figure 14. The parameters used for these tests are provided in test 5 column of table 7. Figure 21 shows the experimental FRFs of the EMS (zoomed on the first mode) in short-circuit, open-circuit and when an optimal resistive shunt is used for four different cases:

- with no NC in the shunt circuit;
- with an NC in parallel and $C_1/C_p = \beta_1 = 0.65$
- with an NC in series and $C_2/C_p = 1.22$ (i.e. $\beta_2 = 0.82$)

Figure 23. FRFs (displacement U to force F_{ext} ratio), around the fourth resonance of the EMS, for different configurations, analogous to figure 4. Comparison of experiments (solid lines) and theory (dashed lines).

- with two NCs in SP configuration with $\beta_{sp1} = \beta_1$ and $\beta_{sp2} = \beta_2$.

These values were chosen because they were those that provided at the same time the best attenuation and avoidance of both saturation and non-linearity for the parallel, series and SP configurations.

Figure 21 shows that the SP configuration is able to shift both the open- and short-circuit eigenfrequencies at the same time, thus allowing the attenuation performance to be improved. The maximum of the FRF of the SP with the optimal value of R_{sh} (i.e. R_{opt}) is close to the intersection point of the corresponding open- and short-circuit FRFs, as expected, and the same occurs for all the configurations considered, in accordance with the analytical approach proposed (see section 4 and figure 4). It has been noticed that the SP tends to be unstable in short-circuit condition and becomes stable once a given value of R_{sh} is achieved. Such a value was 890.5 Ω for the test case of figure 21. This threshold value on R_{sh} was found to get lower and lower once the values of C_1 and C_2 moved farther and farther from the stability limits.

Figure 22 shows the numerical FRFs corresponding to some of the experimental FRFs shown in figure 21, and the agreement is good, proving again the reliability of the analytical model presented herein. Moreover, the effectiveness of the SP is confirmed because it is able to improve the performance of the series configuration of about 2.4 dB and that of the parallel layout of about 7.8 dB on the first mode. Finally, figure 23 shows analogous results for the fourth resonance.

7. Conclusion

This paper has addressed several points regarding the theory and experiments on resistive shunt damping enhanced by the use of negative capacitances (NCs). The most original contributions to the topic are: the use of a novel layout based on the use of two NCs at the same time, able to improve the performance of the traditional NC layouts; the development of a refined multi-mode model for the electro-mechanical system (EMS); the single and multi-mode optimisation strategies as well as analytical formulas to foresee the vibration attenuation level; finally, the analytical treatment of the real circuits used to build the NC. In particular, a multi-mode theoretical model of the EMS has been proposed and reduced to a single degree of freedom in a refined manner, by carefully analysing the piezoelectric patch capacitance dependence on the frequency and using static corrections. This refined description of the patch capacitance is found to be mandatory when dealing with negative capacitance circuits, since it is directly linked to the dynamical stability of the system.

This model enables an analytical formalism to be developed that is common to all the treated resistive shunt layouts: the traditional one (without the NC), an NC in parallel to the piezoelectric patch, an NC in series, and a new configuration using two NCs in series and in parallel. It is first demonstrated that the effect of the NCs is to artificially increase the modal electro-mechanical coupling factors (MEMCF) of the structure by changing the piezoelectric patch capacitance viewed by the shunt; this makes it possible to define an enhanced MEMCF. Then, it is shown that the tuning and the single-mode control performances of the shunt rely only on the enhanced MEMCF and on the intrinsic damping factor of the EMS, in the same way as for traditional R- and RL-shunts. Since the R-shunt performances are increased by the NC, it is also shown that this kind of control leads to a significant broadband attenuation, whereas the usual modest performances of R-shunts are reduced to a single resonance. The proposed new negative capacitance layout is shown to further increase the shunt performance. All these theoretical results are validated by experiments.

Furthermore, the paper explains how to optimise the shunt impedance for the purpose of multi-mode control, explains how to make RCs (i.e. the circuits usually used in practice to build NCs) behave like ICs (i.e. pure NCs) and even develops the analytical treatment of RCs.

Acknowledgments

Appendix A. Analytical treatment for real circuits in series

Here, the equations governing the behaviour of the EMS with an RC in series are described. In this case, the circuit taken into consideration is that of figure 12(b). The impedance Z_{rs} of the shunt circuit is composed by $-C_2$, $-\tilde{R}$ and R_{sh}. Therefore, Z_{rs} can be expressed as in equation (57). Relying on equations (22a)–(c), taking into consideration that

$V = -Z_{\text{rs}}\dot{Q}$ and truncating the model to a single-degree-of-freedom system (see equations (2a) and (9)), the following FRF is yielded:

$$\frac{q_i}{F_i} = \frac{-\Omega^2 C_{\text{p}i} C_2 \tilde{R} R_{\text{sh}} + j\Omega[C_2\tilde{R} + C_{\text{p}i}(-\tilde{R} + R_{\text{sh}})] + 1}{\Omega^4 C_{\text{p}i} C_2 \tilde{R} R_{\text{sh}} - j\Omega^3 A_3 - \Omega^2 A_2 + j\Omega A_1 + \omega_i^2}$$

(A.1)

where:

$$A_1 = 2\xi_i\omega_i + \omega_i^2 C_2\tilde{R} + (\omega_i^2 C_{\text{p}i} + \chi_i^2)(-\tilde{R} + R_{\text{sh}}) \quad \text{(A.2)}$$

$$A_2 = 2\xi_i\omega_i C_2\tilde{R} + 2\xi_i\omega_i C_{\text{p}i}(-\tilde{R} + R_{\text{sh}})$$
$$+ \omega_i^2 C_{\text{p}i} C_2\tilde{R} R_{\text{sh}} + \chi_i^2 C_2\tilde{R} R_{\text{sh}} + 1 \quad \text{(A.3)}$$

$$A_3 = C_2\tilde{R} + C_{\text{p}i}(-\tilde{R} + R_{\text{sh}}) + 2\xi_i\omega_i C_{\text{p}i} C_2\tilde{R} R_{\text{sh}} \quad \text{(A.4)}$$

If we apply the Routh–Hurwitz criterion [16] to equation (A.1), the stability of the EMS with $R_{\text{sh}} = 0$ (i.e. new short-circuit condition) is assured if the following equations are satisfied:

$$C_2 > C_{\text{p}i} + \frac{\chi_i^2}{2\omega_i^2} - \frac{\xi_i}{\omega_i\tilde{R}}$$
$$+ \frac{\sqrt{(2\xi_i\omega_i - \chi_i^2\tilde{R})[2\omega_i(\xi_i^2 - 1) - \chi_i^2\xi_i\tilde{R}]}}{2\omega_i^2\tilde{R}\sqrt{\xi_i}}, \quad \text{(A.5)}$$
$$\texttt{if } \tilde{R} > \frac{2\xi_i\omega_i}{\chi_i^2}$$

or

$$C_2 > C_{\text{p}i}, \quad \texttt{if } \tilde{R} \leqslant \frac{2\xi_i\omega_i}{\chi_i^2} \quad \text{(A.6)}$$

If all the modes of the structure are taken into consideration, the stability conditions of equations (A.5) and (A.6) must be satisfied for all the modes of the EMS. This is a sufficient condition for stability. The use of $R_{\text{sh}} \neq 0$ makes the stability condition difficult to be calculated analytically. There are two ways to calculate the stability conditions:

- numerical simulations, which show that the stability conditions with $R_{\text{sh}} \neq 0$ tend to be less restrictive if compared to the conditions of equations (A.5) and (A.6). Therefore, the condition of equations (A.5) and (A.6) can yet be used to guarantee the stability of the EMS (actually the effect of R_{sh} is that of an added damper);
- if an accurate value of the stability limit is needed, the following system of equations must be solved for each mode to find the stability conditions thanks to the Routh–

Hurwitz criterion:

$$\begin{cases} A_3 > 0 \\ A_2 > 0 \\ A_1 > 0 \\ \dfrac{A_1}{C_{\text{p}i} C_2\tilde{R} R_{\text{sh}}} < \dfrac{A_3 A_2}{(C_{\text{p}i} C_2\tilde{R} R_{\text{sh}})^2} \\ \dfrac{\omega_i^2}{C_{\text{p}i} C_2\tilde{R} R_{\text{sh}}} < \dfrac{[A_1 A_2 A_3 / (C_{\text{p}i} C_2\tilde{R} R_{\text{sh}})^3] - [A_1^2 / (C_{\text{p}i} C_2\tilde{R} R_{\text{sh}})^2]}{(A_3 / (C_{\text{p}i} C_2\tilde{R} R_{\text{sh}}))^2} \end{cases}$$

(A.7)

Once the stability conditions are known, the optimal value of R_{sh} can be derived analytically. Relying on the FRF of equation (A.1) and following the same procedure discussed in section 4.4, the relation between a fixed value of R_{sh} and ω_i^{r} can be found. This relation is expressed by a ninth order equation and a closed formulation for its solution cannot be found. The expression of the equation is quite long and thus we have not added it to the paper. Nevertheless, the reader can find it easily by using the same approach presented in section 4.4 (see equations (44) and (45)). Such an equation provides nine solutions (one of them is the trivial solution equal to zero). Then, the physical solution must be looked for so that this procedure can be used to draw the curve linking R_{sh} and H_i^{max} and thus mono- and multi-modal optimisations can still be carried out.
